The above summary indicates how the discoveries of physics are applied to many branches of engineering; and a knowledge of the laws of physics, and of the results of physical researches, appears, therefore, essential for the successful prosecution of engineering works. The very intimate relation of mechanical science to mathematics and physics, and the indebtedness of engineers to men of science outside the ranks of their own profession, are, indeed, evidenced by the roll of the Presidents of Section G, containing the names of Dr. Robinson, Mr. Babbage, Prof. Willis, Prof. Walker, and Lord Rosse.

Chemistry in Relation to Engineering.—Gas-making is in reality a chemical operation on a large scale, consisting in the destructive distillation of coal, the purification and collection of the resulting carburetted hydrogen, and the separation and utilisation of the residual products. Chemistry, accordingly, holds a very important place in the requirements of the gas engineer.

The manufacture of iron, steel, and other metals, and the formation of alloys, are essentially chemical operations; and the Bessemer and Gilchrist processes, by which steel is produced in large quantities directly from cast iron, by eliminating a portion of the carbon contained in it, and also the injurious impurities, silicon and phosphorus, in place of the former costly and circuitous method of removing the carbon from cast iron to form wrought iron, and then combining a smaller proportion of carbon with the wrought iron to form steel, are based on definite chemical changes, and necessitated chemical knowledge for their development.

Chemical analysis is needed for determining the purity of a supply of water, or the nature and extent of its contamination; and Dr. Clarke's process for softening hard water, by the addition of lime water, depends upon a chemical reaction. The methods, also, of purifying water by filtration, shaking up with scrap iron, and aëration, are chemical operations on an extensive scale; and their efficiency has to be ascertained by chemical tests.

Cements and mortars depend for their strength and tenacity, when mixed with water, upon their chemical composition and the chemical changes which occur. The value of Portland cement requires to be tested quite as much by a chemical analysis of its component parts as by the direct tensile strength of its briquettes; for an apparently strong cement may contain the elements of its own disruption, in a moderate proportion of magnesia or in an excess of lime. The chemical change which has been found to occur in the Portland cement of very porous concrete exposed to the percolation of sea-water under considerable pressure, by the substitution of the magnesia in sea-water for the lime in the cement, if proved to take place even slowly under ordinary circumstances, would render the duration of the numerous sea works constructed with Portland cement very precarious, and necessitate the abandonment of this very convenient material by the maritime engineer.

Explosives, which have rendered such important services to engineers in the construction of works through rock and the blasting of reefs under water, as well as for purposes of attack and defence, form an important branch of chemical research. The uses of gun-cotton as an explosive agent, though not for guns, have been greatly extended by the investigations of Sir Frederick Abel, and by the discovery that it can be detonated, when wet and unconfined, by fulminate of mercury; whilst smokeless powder, a more recent chemical discovery, seems likely, by its application to firearms, to produce important modifications in the conditions of warfare. The progress achieved by chemists in other forms of explosives has been marked by their successive introduction for blasting in large engineering works. Thus the removal of the rock in driving the Mont Cenis tunnel, in 1857–71, was effected by ordinary blasting powder; whilst the excavation of the longer St. Gothard tunnel, in 1872–82, was accomplished by the more efficient explosive dynamite (*Proceedings Inst. C.E.*, vol. xcv. p. 266). Moreover, the first great blast for removing the portion of Hallett's Reef which obstructed the approach to New York Harbour, was effected mainly by dynamite, together with vulcan powder and rendrock, in 1876; whereas the far larger Flood Rock, in mid-channel, was shattered in 1885 by rackarock, a mixture of potassium chlorate and nitrobenzol, and a much cheaper and a more efficient explosive under water than dynamite (*Ibid.*, vol. xcv. pp. 267–270). Rackarock is one of the series of safety explosives first investigated by Dr. Sprengel in 1870, which, consisting of a solid and a liquid, is safely and easily mixed for use; and these materials, being harmless previously to their admixture, can be stored in large quantities without risk (*Journal of the Chemical Society*, August 1873). The cost also of this large blast was greatly reduced by the sympathetic explosion of the bulk of the cartridges by the detonation of a series of primary exploders, placed at intervals along the galleries and fired simultaneously by electricity from the shore.

The utilisation of sewage belongs to agricultural chemistry; and the deodorisation of sewage, and its conversion into a commercial manure, are chemical processes. The disposal of sewage by irrigation is a branch of agriculture; and the innocuous character of the effluent fluid, discharged into the nearest stream or river, has to be ascertained by chemical analysis. Chemists have the opportunity of benefiting the community, and at the same time acquiring a fortune, by discovering an economical and efficient process for converting sewage on a large scale into a profitable saleable manure, so that inland towns may not have to dispose of their sewage at a loss, and that towns situated on tidal estuaries or the sea-coast may no longer discharge their sewage into the sea, but distribute it productively on the land.

The purifying of the atmosphere from smoke, rendered increasingly expedient by the growth of population, and the prevention of the dense fogs caused by it, by some practical method for more thoroughly consuming the solid particles of the fuel, still await the combined efforts of chemists and engineers.

Geology in Relation to Engineering.—A knowledge of the superficial strata of the earth is important for all underground works, and essential for the success of mining operations. Geology is indispensable in directing the search for coal, iron ore, and the various metals; and the existence of faults or other disturbances may greatly modify the conditions. The value of geology to the engineer is not, however, confined to the extraction of minerals, for it extends, more or less, to all works going below the surface.

The water-supply of a district, in the absence of a suitable river or stream, is dependent on the configuration and geology of the district; and the spread of London before the extension of waterworks, as pointed out by Prof. Prestwich, had to be confined to the limits of the gravel subsoil, in which shallow wells gave access to the water arrested by the stratum of underlying London clay. The sinking also of deep wells for a supply of water, and the depth to which they should be carried, are determined by the nature of the formation, the position of faults, and the situation of the outcrop of the water-bearing stratum. A geological examination, moreover, of a site proposed for a reservoir, to be formed by a reservoir dam across a valley, has to be made to ascertain the absence of fissures and the soundness of the foundation for the dam.

In the driving of long tunnels, the nature and hardness of the strata and their dip, the prospects of slips, and the possibility of the influx of large volumes of water, are geological considerations which affect the designs and the estimates of cost. The excavations also of large railway cuttings and ship canals are considerably affected, both as regards their side slopes and cost, by the nature and condition of the strata traversed.

Meteorology in Relation to Engineering.—The maximum pressure that may be exerted by the wind has to be allowed for in calculating the strains which roofs, bridges, and other structures are liable to have to bear in exposed situations; and con-

[illegible] records of anemometers for long periods are required for determining this pressure. The force of the wind also, and the direction, duration, and period of occurrence of severe gales, are important to the maritime engineer for estimating the effect of the waves in any special locality, for determining the quarter from which shelter is needed, and for ascertaining the seasons most suitable for the execution of harbour works, the repair of damages, and the carrying out of foundations of lighthouses and beacons on exposed rocks. The harbour engineer must, indeed, of necessity be somewhat of a meteorologist, for the changes in the wind and weather, the oscillations of the barometer, and the signs of an approaching storm are indications to him of approaching danger to his works, which he has to guard against; for the sea is an insidious enemy which soon discovers any weak spot, and may in a few hours destroy the work of months.

Continuous records of rainfall, as collected regularly by Mr. Symons from numerous stations in the United Kingdom, are extremely valuable to engineers for calculating the probable average yield of water from a given catchment area, the greatest and least discharges of a river or stream, the size of drainage channel needed to secure a low-lying area from floods, and the amount of water available for storage or irrigation in a hot, arid district. The loss of water by evaporation at different periods of the year, and under different conditions of soil and climate, the effect of percolation in reducing evaporation, and the influence of forests and vegetation in increasing the available rainfall, while equalising the flow of streams, are subjects of equal interest to hydraulic engineers and meteorologists.

Countries periodically visited by hurricanes, cyclones, or earthquakes, necessitate special precautions, and special designs for structures; and every additional information as to the force and extent of these visitations of nature is of value in enabling engineers to provide more effectually against their ravages.

Benefits conferred by Engineering upon Pure Science.—Engineering is generally concerned in the application of the researches of science for the benefit of mankind, and not in the extension of the domain of pure science, which necessitates greater concentration of attention and study than the engineer in practice is able to devote to it. Engineers, however, though never able to repay the ever-increasing debt of gratitude which they owe to past and present investigators of science, except in rendering these abstract researches of practical utility, have, nevertheless, been able incidentally to promote the progress of science. Thus mechanical science, by the construction of calculating machines, the planimeter, integrating machines, the tide-predictor and tidal harmonic analyser of Lord Kelvin, the self-registering tide-gauge, and various other instruments, has lightened the labours of mathematicians; whilst excavations for works, and borings have assisted the investigations of geologists. The mechanical genius of Lord Rosse led mainly to the success of the gigantic telescope, which has revealed so many secrets of the heavens; and the rapidity of locomotion, due to the labours of engineers, has greatly facilitated astronomical observations and physical discoveries, besides promoting the concourse of scientific men and the diffusion of knowledge. Electrical engineering, moreover, is so closely allied to electrical physics that the development of the one necessarily promotes the progress of the other. The observations also conducted by hydraulic and maritime engineers in the course of their practice aid in extending the [illegible] upon which the science of meteorology is based.

Engineering an Experimental Science.—Engineering, so far as it is based on mathematics, is an exact science, and the strains due to given loads on a structure can be accurately determined; but the strength of the materials employed has to be ascertained before any structure can be properly designed. Accordingly, the resistance of materials to tension, compression, and flexure, has to be tested, and their limit of elasticity and breaking weight determined. Thus, previously to the construction by Robert Stephenson, of the Britannia Tubular Bridge, the first wrought-iron girder bridge of large span erected, [illegible] experiments on various forms of wrought iron were [illegible] the eminent mathematician and mechanician [illegible] Hodgkinson, who had previously indicated the proper [illegible] for cast iron girders, and to whom the success of the [illegible] across the Menai Straits was in great measure due [illegible] Conway Tubular Bridges, Edwin Clark, [illegible] the [illegible] always now made of the materials [illegible] during the progress of any large [illegible] bridges are also subjected to severe [illegible] before being opened for public traffic, by which the safety of the structures and their rigidity, as measured by the amount of deflection, are ascertained, serving as a guide for subsequent designs.

Numberless experiments have been made on the flow of water in open channels, over weirs, through orifices, and along pipes; and the influences of the nature of the bed, the slope, depth, and size of channel, have been investigated by various hydraulicians. Mr. Thomas Stevenson measured the force of waves at some places on the Scotch coast ("The Design and Construction of Harbours," Thomas Stevenson, 3rd ed. pp. 52-56); Prof. Osborne Reynolds has examined the laws of tidal flow in a model of the inner estuary of the Mersey, and in specially shaped experimental models ("British Association Reports" for 1889, 1890, and 1891); and I have found it possible, in small working models of the Mersey and Seine, not merely to reproduce the configuration of the bed of the estuary out to sea, but also to observe the effects of different forms of training works in modifying sandy estuaries.[1] Mr. William Froude, after his retirement from active practice, devoted his abilities to experiments on the motion and resistance of ships in water, which have proved of inestimable value to the naval architect, and which formed the subject of his presidential address to this Section in 1875.

Electrical engineering is specially adapted for experimental investigation; and, in this branch, theory and practice are so closely allied that some of the most eminent exponents of the theory of the subject, such as Lord Kelvin and Dr. Hopkinson, have developed their theories into practical results. In most other branches, the investigator is generally distinct from the engineer in large practice; but it may be safely said that an able investigator and generaliser in engineering science, as, for instance, the late Prof. Rankine, accomplishes work of more value to the profession at large than the practical engineer, who, in the world's estimation, appears the more successful man.

Every branch of engineering science is more or less capable of being advanced by experimental investigations; and when it is borne in mind that the force of waves, the ebb and flow of tides in rivers, the influences of training works in estuaries, and the motion of ships at sea have been subjected to experimental research, it appears impossible to assign a limit to the range of experiments as a means of extending engineering knowledge. Problems of considerable interest, which can only be solved by experiments or by comprehensive generalisations from a number of examples, must frequently present themselves to engineers in the course of their practice, as they have to myself; and engineers would render a great service to the profession if they would follow up the lines of investigation thus suggested to them, in the true spirit of scientific inquiry.

Failures of Works due to Neglect of Scientific Considerations.—Before the amount and distribution of the stresses in structures were thoroughly understood, a disposition was naturally evinced to err on the side of excessive strength; and the materials in the various parts of the structure were not suitably proportioned to the load to be borne, resulting in a waste of materials and too great an expenditure on the works. Thus some of the early high masonry reservoir dams in Spain exhibit an excessive thickness towards the top, imposing an unnecessary load on the foundations; and in many of the earlier iron girder bridges more material was employed than was required for stability, and it was not properly distributed. Boldness engendered by increased experience, and dictated by motives of economy, has tended to make the engineers of the present day pursue an opposite course; and, under these circumstances, the correct calculation of the strains, the exact strength of the materials, and a strict appreciation of the physical laws affecting the designs become of the utmost importance.

The failures of many bridges may be explained by errors in design, defects in construction, or by economy carried beyond the limits of safety in pushing forward railways in undeveloped countries; but other failures are attributable to a disregard or underestimation of the influence of physical causes. Thus the Tay Bridge disaster, in 1879, was due to underestimating the amount and effect of the wind-pressure in an exposed situation, where it acted with a considerable leverage, owing to the height of the bridge, and was inadequately provided against by the

[1] *Proceedings* of the Royal Society, vol. xlv. pp. [illegible], and plates 2-4; vol. xlvii. p. [illegible]; and "Amélioration de la Partie Maritime des Fleuves, y compris leur Embouchure," L. F. Vernon-Harcourt, Paris Inland Navigation Congress, 1892, pp. 27-2[illegible], and [illegible], and plate [illegible].

small transverse width of the piers in proportion to their height, which were further weakened by bad workmanship in the bracing of their columns. The bursting of the Bouzey masonry dam in France this year must be attributed to an inadequate thickness at part of the cross-section, producing a tensional strain on the inner face with the reservoir full, aided by the instability resulting from a fissured foundation. The overthrow of the outer arms of the Madras breakwaters, during a cyclone in 1881, may be traced to an inadequate estimate of the force of the waves in a storm, in deep water, and with a great fetch across the Indian Ocean, beating against the portions of the breakwaters directly facing their course; for these outer portions, running nearly parallel to the coast-line, were not made any stronger than the inner portions placed at right angles to the shore and the direction of the waves, and situated for the most part in shallower water. The erosion of the bed of the Ganges Canal on the first admission of the water, necessitating the erection of weirs at intervals to check the current, resulted from an error in the calculated discharge of the channel with the given inclination, and the consequent undue velocity of the stream, producing scour. The failure of the jetty works at the outlet of the Rhone to effect any permanent deepening of the channel over the bar, was due to the unsuitable direction given to the outlet channel in view of the physical conditions of the site, and the concentration of all the discharge, and consequently all the alluvium carried down, into a single mouth, whereby the rate of deposit in front of this outlet has been considerably increased. The excessive cost, and consequent stoppage, of the Panama Canal works, though due to a variety of causes, must be partly attributed to want of due consideration of the strata to be excavated: for a cutting of 300 feet in depth, which may be possible in rock, becomes impracticable when a considerable portion has to be executed in very treacherous clay.

Occasionally failures of works may be attributed to exceptional causes or peculiarly unfavourable conditions; but in most cases, as in the instances given above, they are the result of errors or deficiencies in design, which might have been avoided by a more correct appreciation of the physical conditions involved.

Scientific Training of Engineers.—In most professions, preliminary training in those branches of knowledge calculated to fit a student for the exercise of his profession is considered indispensably necessary; and examinations to test the proficiency of candidates have to be passed as a necessary qualification for admission into the Army, Navy, Church, Civil Service, and both branches of the law. Special care is taken in securing an adequate preliminary training in the case of persons to whom the health of individuals is to be entrusted, not merely by experience in hospitals, but also by examinations in those branches of science and practice relating to medicine and surgery, before the medical student can become a qualified practitioner. If so much caution is exercised in protecting individuals from being attended by doctors possessing insufficient knowledge of the rudiments of their profession, how much more necessary should it be to ensure that engineers are similarly qualified, to whom the safety and well-being of the community, as well as large responsibilities in regard to expenditure, are liable to be entrusted! The duty of the engineer is to apply the resources of nature and science to the material benefit and progress of mankind; and it, therefore, seems irrational that no guarantee should be provided that persons, before becoming engineers, should acquire some knowledge of natural laws, and of the principles of those sciences which form the basis of engineering. The Institution of Civil Engineers has, indeed, of recent years required some evidence of young men having received a good education before their admission into the student class; but some of the examinations accepted as sufficient for studentship, such as a degree in any British university, afford no certainty in themselves that the persons who have passed them possess any of the qualifications requisite for an engineer; and it is quite unnecessary to become a student of the Institution in order to become an engineer. The Council of the Institution has no doubt been hitherto deterred from proposing the establishment of an examination in mathematics and natural science, as a necessary preliminary to becoming an engineer, by the remembrance that some of the most distinguished engineers of early days in this country were self-taught men; but since those days engineering and the sciences upon which it is based have made marvellous advances; and in view of these developments, and the excellent theoretical training given to foreign engineers, it is essential that British engineers, if they desire to retain their present position in the world, should arrange that the recruits to their profession may be amply qualified at their entrance in theoretical knowledge, in order to preserve the standard attained, and to be in a position to achieve further progress. No amount of preliminary training will, indeed, necessarily secure the success of an engineer, any more than the greatest proficiency would be certain to lead the medical student to renown as a physician or surgeon: but other conditions being equal, it will greatly promote his prospects of advancement in his profession, and his utility to his colleagues and the public. The engineers of the past achieved great results in the then early dawn of engineering knowledge, by sound common sense, a ready grasp of first principles and of the essential points of a question, capacity for acquiring knowledge, power of managing men and impressing them with confidence, and shrewdness in selecting competent assistants. These same qualities are still needed for success in the present day, coupled with an opportunity of exhibiting them; but far more knowledge of mathematics and other sciences is required now, owing to the enormous advances effected, if the progress of engineering science is to be maintained. Even though in some branches, engineers in large practice may not have the time, or retain the requisite facility, for solving intricate mathematical problems, they should be able readily to comprehend the full bearing of the principles presented, and to understand the nature of the solutions put before them, which nothing but the scientific faculty implanted by early training in mathematics and physics can adequately secure.

A qualifying examination for engineers would usefully stop persons at the outset from entering the profession, who failed to evince the possession of the requisite preliminary knowledge: it would indicate, by the subjects selected, the kind of training best calculated to fit a person to become a useful engineer; and it would protect the public, as far as practicable, from the injuries or waste of money that might result from the mistakes of ill-qualified engineers.

Specialising in Engineering.—Some branches of engineering have for a long time been kept distinct from others, such as the construction of steam-engines, locomotives, and marine engines, ship-building, heavy ordnance, hydraulic machinery, and other purely mechanical works, one or more of which have been treated as specialities by certain firms, and also gas lighting, and, more recently, electric lighting. In the department, however, of civil engineering in its narrower signification, as distinguished from mechanical engineering, engineers of former times were regarded as equally qualified to undertake any of the branches of public works; and the same engineer might be entrusted with the execution of roads, railways, canals, harbours, docks, sewerage works, and waterworks; while even steamships were not excluded from the category in Brunel's practice. The engineer of to-day, indeed, would be lacking that important factor for success, common sense, if he declined to execute any class of works which he might be asked to undertake; and a variety of works is very useful to the engineer in enlarging his views and experience, as well as in extending the range of his practice. The tendency, however, now in engineering, as in medicine, is for the engineer's practice to be confined to the special branch in which he had had most experience; a result which cannot fail to be beneficial to the public, and calculated to promote the progress of each branch. The powers of the human mind are too limited, and life is too short, for engineers to be able to acquire, in the present day, equal proficiency in the theory and practice of the several branches of engineering science, with their ever-widening scope and development; and, as in the domain of abstract science, general progress will be best achieved in engineering science by the concentration of the energies of engineers in the advancement of their special line of practice.

Value of Congresses on Special Branches of Engineering.—The scope of engineering science is extending so fast that it is impossible for the Institution of Civil Engineers, which, as the parent society, embraces every branch within its range of subjects, to give more than a very limited time for the consideration and discussion of papers relating to the non-mechanical branches of the profession comprised in public works. Mechanical, electrical, and gas engineers have special societies of their own for advancing their knowledge and publishing their views and experience, while sharing equally with the other branches in the benefits of the older Institution.

Congresses accordingly afford a valuable opportunity for railway, hydraulic, and sanitary engineers of expressing their views, and enlarging their experience by consultation and discussion with engineers of various countries. My experience of the six maritime, inland navigation, and water-works international congresses I have attended in England and abroad, has convinced me of the very great value of such meetings in collecting information, comparing views, and obtaining some knowledge of foreign works and methods; whilst the acquaintances formed with some of the most celebrated foreign engineers, afford opportunities of gaining further information about works abroad, and deriving experience from their progress and results.

Engineering Literature.—Lawyers have been defined as persons who do not possess a knowledge of law, but who know where to find the law which they may require. It may be hoped that a similar definition is not applicable to engineers; but with the rapid increase of engineering literature, it is most desirable that engineers should be able readily to refer to the information on any special subject, or descriptions of any executed works, which may have been published. Much valuable matter, however, is buried in the proceedings of engineering and scientific societies, and in various publications; and often a considerable amount of time is expended in fruitless search. This great waste of time and energy, and the loss of available information involved, led me a few years ago to suggest that a catalogue of engineering literature ought to be made, arranging the lists of publications relating to the several branches under separate headings. There is a possibility that this arduous and costly task may be partially accomplished in separate volumes; and, at any rate, the first step has been effected by the publication, under the auspices of the Paris Inland Navigation Congress of 1892, of a catalogue of the publications on inland navigation. A start has also been made in France, Italy, and England, towards the preparation of a similar catalogue on maritime works, which it may be hoped means one day will be found to publish on the meeting of some future congress. Engineers who have searched, even in the best libraries, for the published information on any special subject, will appreciate what a great boon an engineering subject catalogue would be to the profession, and indirectly to the public at large.

The occasional publication of comprehensive books on special branches of engineering, and concise papers on special subjects, by competent authorities, are extremely valuable in advancing and systematising engineering knowledge; but the time and trouble involved in the preparation of such publications must, like the organising of congresses, be regarded as a duty performed in the interests of the profession and science, and not as affording a prospect of any pecuniary benefit.

Concluding Remarks.—In this address I have endeavoured, though very imperfectly, to indicate how engineering consists in the application of natural laws and the researches of science for the benefit and advancement of mankind, and to point out that increased knowledge will be constantly needed to keep pace with, and to carry on, the progress that has been made. The great advantages provided by engineering works in facilitating communications and intercourse, and consequently the diffusion of knowledge, in increasing trade, in extending civilisation to [illegible], in multiplying the comforts of life, and affording [illegible] facilities of enjoyment and change of scene, may be [illegible] readily acknowledged; but the more gradual and [illegible], though not less important, benefits effected by [illegible] works are not so fully realised.

A comparison of engineering with the other chief branch of applied science, medicine, exhibits some similarities and [illegible]. In both professions, the discoveries of science are [illegible] for the benefit of mankind; but whilst physicians devote [illegible] to individuals, engineers are concerned in [illegible] being of the community at large. Persons [illegible] doctor when they are attacked by disease, or [illegible] accident; but they eagerly resort for enjoy[illegible] [illegible], mountain tramways, piers, great [illegible]; and they frequently avail themselves [illegible] locomotion to complete their [illegible] change of air and climate. Physicians [illegible] are ill: whereas engineers en[illegible] [illegible] and efficient drainage, to main[illegible] [illegible] respect, the evident results of [illegible] readily realised than the invisible, [illegible] benefits of engineering works. Statistics alone can reveal the silent operations of sanitary work; and probably no better evidence could be given of the inestimable value of good water and proper drainage on the health of the population of large towns, when aided by the progress of medical science, than the case of London, where, towards the close of the last century, the death-rate exceeded the birth-rate, and the numbers were only kept up by constant immigrations: whereas now, in spite of the vast increase of the population and the progressive absorption of the adjacent country into the ever-widening circle of houses, the number of births exceed the deaths by nearly nine hundred a week.

In engineering, as in pure science, it is impossible to stand still; and engineers require to be ever learning, ever seeking, to appreciate more fully the laws of nature and the revelations of science, ever endeavouring to perfect their methods by the light of fresh discoveries, and ever striving to make past experience and a wider knowledge stepping-stones to greater achievements. Engineers have a noble vocation, and should aim at attaining a lofty ideal; and, in the spirit of the celebrated scientific discoverers of the past, such as Galileo, Newton, Laplace, Cavendish, Lyell, and Faraday, should regard their profession, not so much as an opportunity of gaining a pecuniary reward, as a means of advancing knowledge, health, and prosperity.

The remarkable triumphs of engineering have been due to the patient and long-continued researches of successive generations of mathematicians, physicists, and other scientific investigators; and it is by the utilisation of these stores of knowledge and experience that engineers have acquired renown. A higher tribute of gratitude should perhaps be paid to the noble band of scientific investigators who, in pursuit of knowledge for its own sake, have rendered possible the achievements of engineering, than to those who have made use of their discoveries for the attainment of practical benefits; but they must both be regarded as co-workers in the promotion of the welfare of mankind. The advancement of science develops the intellectual faculties of nations, and enlarges their range; whilst the resulting progress in engineering increases their material comforts and prosperity. If men of science, by closer intercourse with engineers, could realise more fully the practical capabilities of their researches, and engineers, by a more complete scientific training, could gain a clearer insight into the scientific aspect of their profession, both might be able to co-operate more thoroughly in developing the resources of nature, and in furthering the intellectual and material progress of the human race.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

SECOND SPRINGFIELD MEETING.

THE forty-fourth meeting of the American Association for the Advancement of Science was held at Springfield, Mass., August 29 to September 4, being the second meeting held at that city; the first was in 1859.

In the early history of the Association frequent meetings were held in New England, but fifteen years have passed since the last preceding New England meeting, held at Boston. The social and intellectual life of all New England cities ranks high, and the Association found a most appreciative and hospitable community.

A copy of the address of the retiring President, Dr. Daniel G. Brinton, on "The Aims of Anthropology," has already been sent to NATURE. It was a matter for regret that the author was unable to attend and read it personally.

The vice-presidential addresses were not quite so many as usual, owing to the resignation of Profs. Holden and Jordan as presidents of the Sections of Astronomy and Zoology, respectively, because of the change in place of meeting from California, where they reside, and where it was intended to meet if the trans-continental railroads had reduced fares sufficiently. The addresses delivered were by W. L. Stevens, on "Recent Progress in Optics"; William McMurtrie, on "The Relation of the Industries to the Advancement of Chemical Science"; William Kent, on "The Relation of Engineering to Optics"; J. Hotchkiss, on "The Geological Survey of Virginia, 1835–1841: its History and Influence in the Advancement of Geologic Science"; J. C. Arthur, on "The Development of Vegetable Physiology"; F. H. Cushing, on "The Arrow"; and B. E. Fernow, on "The Providential Function of Government in Relation to Natural Resources."

One of the first and most important matters of business presented was in reference to the proposed meeting of the British Association in Toronto in 1897. The writer offered a resolution cordially inviting the Association, in case they decide to accept the invitations already sent them from Toronto to hold the meeting there, to attend our meeting also as our guests, and requesting them to send early notice of the time of meeting to the Permanent Secretary of our Association, that ample time may be had to make suitable arrangements, and to renew the delightful memories of the Philadelphia meeting in 1884. This was referred to the Permanent Secretary with power.

Should the Association come to America as proposed, it seems probable that the long-deferred San Francisco meeting will then be held, as it is believed that many visitors will desire to cross the continent by the Canadian Pacific Railroad, which was incomplete at the time of the Montreal meeting in 1884; but many who attended that meeting went as far west as the road would then take them. As Sir Wm. C. Van Horne, President of that road, is a member of the British Association, and has been a member of ours, his influence is relied on to secure favourable rates of transportation. Still another factor is that the Christian Endeavour Societies expect to meet at San Francisco in 1897, and as they are a mighty army—70,000 attended the Boston meeting this summer—the railroads usually offer exceptional rates to secure their patronage, and the Associations can share in the benefit of the reduction.

Of the 207 papers read before the several Sections, many might be mentioned. The subject of colour and colour standards, on which Mr. Pillsbury had an article in a recent number of NATURE, was presented by him and others, and resolutions were passed looking toward the establishment of a colour standard. E. R. von Nardroff exhibited and described a new apparatus for studying colour phenomena. Colour photography was discussed and photographs exhibited by F. E. Ives.

A process for photographing the vocal cords in action has been discovered by F. S. Muckey and Wm. Hallock, and it is found that the pitch of a note is raised by rotating the arytenoid cartilages without increasing the tension of the cords, just as a violinist makes high notes by shortening the string with his finger. Voice analysis also has been studied by Messrs. Hallock and Muckey, by an ingenious system of resonators for the fundamental and seven overtones, covering three octaves from the fundamental C. These resonators are so arranged that the vibration of each causes the flickering of a tiny gas jet, and by observing these it can be seen which of the overtones are sounding, and by drawing straight or wavy lines to correspond with each of these, a picture of the tone can be made. This will enable a singer to see every tone in his voice, and learn wherein he needs to correct it.

The Weather Bureau of the United States supplied experts to fill up an afternoon in a joint meeting of four Sections. Willis L. Moore, the new chief of the bureau, spoke of the work in hand and that contemplated. An elaborate scheme of observation of upper strata of the air by kites and balloons and kite-balloons is to be carried out; and regular observations are to be made of "sensible temperature" by the wet bulb thermometer.

Frank N. Bigelow, in his paper on solar magnetic radiation and weather forecasts, made some very remarkable statements. The sun, he says, throws out curved lines of magnetic force. These are connected with sun-spots, and with storms on the earth. They have been studied by him so carefully that he fixes the time of the sun's axial revolution more accurately than ever before at 26·07928 days, with a probable error only in the last or possibly the two last figures. A surprising inference from his studies is that the earth has a crust 800 miles thick, and the sun has also a crust. Future investigation will supply data for a long forecast of seasonal weather conditions, years ahead. Cleveland Abbe followed with a paper on clouds and their nomenclature, and Alfred J. Henry with some very beautiful cloud photographs.

Electro-metallurgy has made rapid strides, and a paper on calcium carbide, by P. de Chalmot and J. T. Morehead, gave an account of the process used at their works in Spray, N.C., for cheap production of this compound by smelting together lime and coke in the electric furnace. This enables them to produce acetylene, the illuminating principle of gas, much cheaper than any other process.

A paper on the new process of making white-lead by electric action was read by R. P. Williams before the American Chemical Society, which met at Springfield two days earlier than the Association. Mr. Williams describes the process, which will work a revolution in this industry. Instead of acetate of lead, as in the old process, sodium nitrate is used together with sodium bicarbonate. A number of cells are filled with the solution, with plates of lead at one pole and of copper at the other. The current from a dynamo causes nitric acid to be liberated and to combine with the lead. A number of reactions occur, with the final production of white-lead in a very fine and uniform state and of superior colouring quality. The chemicals can be re-used indefinitely. As many as 500 pounds have already been made at one charge.

The Economic Section has always been one of great popular interest. The monetary question, monometallism or bimetallism, by J. W. Sylvester and Henry Farquhar; taxation in the United States, by Edward Atkinson; growth of great cities, by E. L. Corthell; manual training in horticulture, by W. R. Lazenby, were among the matters treated of. An effort was made to widen the scope of this Section by a change of name. Its name—Section of Economic Science and Statistics—was deemed peculiarly undesirable, and after much discussion of the respective merits of "sociology" and "social and economic science," the latter title was adopted as the name of Section I.

Buffalo was unanimously chosen as the next place of meeting, following the practice of the Association to meet at that city every tenth year, beginning with 1866, when 79 members there reorganised the Association after six years of suspended animation, during which no meeting had been held.

The time for meeting was much controverted. The Council recommended a change to Monday as the opening day, which met decided opposition, and on an informal vote 30 were opposed to it and only 27 favoured it; but opposition at length gave way, and the next meeting will begin on Monday, August 24, 1896, at Buffalo.

Officers elected were—President: Edward D. Cope, of Philadelphia. Vice-Presidents: A, Mathematics and Astronomy, William E. Story of Worcester; B, Physics, Carl Leo Mees of Terre Haute, Ind.; C, Chemistry, W. A. Noyes of Terre Haute, Ind.; D, Mechanical Science and Engineering, Frank O. Marvin of Lawrence, Kan.; E, Geology and Geography, B. K. Emerson of Amherst; F, Zoology, Theodore N. Gill of Washington; G, Botany, N. L. Britton of New York city; H, Anthropology, Alice C. Fletcher of Washington; I, Social Science, William R. Lazenby of Columbus, O. Permanent Secretary: F. W. Putnam of Cambridge. General Secretary: Charles R. Barnes of Madison, Wis. Secretary of the Council: Asaph Hall, Junr., of Ann Arbor, Mich. Secretaries of the Sections: A, Mathematics and Astronomy, Edwin B. Frost of Hanover, N.H.; B, Physics, Frank P. Whitman of Cleveland, O.; C, Chemistry, Frank P. Venable of Chapel Hill, N.C.; D, Mechanical Science and Engineering, John Galbraith of Toronto, Can.; E, Geology and Geography, A. C. Gill of Ithaca, N.Y.; F, Zoology, D. S. Kellicott of Columbus, O.; G, Botany, George F. Atkinson of Ithaca, N.Y.; H, Anthropology, John G. Bourke, United States Army; I, Social Science, R. T. Colburn of Elizabeth, N.J. Treasurer, R. S. Woodward of New York.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

August Meteors. Red Spot on Jupiter.

As supplementary to my paper on the August meteors (NATURE, No. 1347, August 22) and to Prof. A. S. Herschel's interesting letter on the same subject (No. 1349, September 5), I may note that a further comparison of the recent observations has revealed two additional instances of doubly observed meteors.

On August 11, 10h. 59m., Prof. Herschel at Slough recorded a meteor equal in brightness to a first magnitude star and moving swiftly along a path of 22½° from 264° + 52° to 252° + 31°, or from the head of Draco into Hercules. The meteor left a long, thin, white streak for 2 secs., and the duration of flight was estimated as 1 sec. Mr. H. Corder, at Bridgwater, observed the same object, noting the time as 10h. 58m., and the apparent path as 23° + 53½° to 14° + 50° between Cassiopeia and Andromeda.

The meteor was evidently a Perseid, and had a radiant at 30° + 57°. It was first seen when at a height of 95 miles above Oxford, and disappeared when 61 miles above Devizes. Its real length of path was 53 miles, and the earth point is indicated in the English Channel about 10 miles south of Lyme Regis, Dorsetshire.

On August 11, 11h. 43m., Prof. Herschel mapped a small bolide, rivalling Jupiter in brightness, and traversing with moderate speed a course of 15° from 229° + 50° to 225° + 44°, or from near ι Draconis to the head of Bootes. Duration of flight 1·5 sec.; the nucleus was evenly bright all the way, and it left a streak for 3 secs. Mr. Corder registered the same meteor, and gives the time as 11h. 42m., magnitude equal to Jupiter, and path as 60° + 62½° to 70° + 64° in Camelopardus. This object was also a Perseid, the radiant being at 32° + 52° near the cluster at χ Persei. The meteor at its first appearance was 75 miles high above a point 5 miles N. of Stratford-on-Avon, and at its disappearance 52 miles high over a place 5 miles W.N.W. of Great Malvern. Its real length of path was 34 miles, and earth point 6 miles S.E. of Aberdare.

Red Spot on Jupiter.—When twilight became too strong for comet-seeking on the morning of August 25 last, I turned my 10-inch reflector on Jupiter and saw the red spot, indefinitely, near its central transit. The planet had only just risen above the tops of some houses in this locality, and the telescopic image was by no means good, but I estimated the transit of the spot occurred at 4h. 24m. A.M. (August 24, 16h. 24m.), or about 9·4m. after Mr. Marth's zero meridian, System II., so that the longitude of the spot was 5°·7. The shouldering of the great south equatorial belt, east of the spot, was very conspicuous, and afforded an excellent guide to the position of the latter. A few minutes after the transit of the red spot I noticed a large white spot on the north side of the north equatorial belt, passing the central meridian. A power of 312 was used in these observations.

Bristol, September 7.

Curious Optical Phenomenon.

The following description of an optical phenomenon, and its probable explanation, may be of interest. It will be observed that a similar experience occurring to one not accustomed to making optical experiments would very probably have caused him to believe that he had seen a ghost. It is therefore of importance psychologically.

The facts observed were as follows:—At about 1 A.M., August 26, I went to my bedroom; to get to it I had to pass through a small room which I used as a study. On entering it, though it was dark, and I had no lamp, the small room seemed brightly illuminated, about as bright as an 8 c.p. lamp would make it, apparently. To one side of a window in the room I saw a man standing, whom I recognised to be myself. The whole impression was very vivid and clear.

So far nothing was observed beyond what is described in the ordinary ghost story. I was much occupied with the consideration of a problem at which I had been working, and did not at first grasp the full signification of what I saw. On turning my head, the figure disappeared, but on looking towards the window, through which a very faint line came, the image reappeared. I then noticed that it was apparently standing in a position occupied, as I knew, by a large table. On more close examination, without, however, moving from the spot where I was standing, I saw that it had changed, and that it did not appear to have features; then it appeared to be flat against the wall, and I finally recognised it as an after-image of a shadow. On my first seeing it, however, it did not have this appearance at all, and I had evidently mentally supplied the features as one always does to the face of a friend who is seen at a distance which is really too great to admit of actual recognition.

I then got the impression of having seen the shadow before, and on considering the matter a few seconds, remembered that it was just before I had started for my room. I had been working in another room, endeavouring to solve a physical problem for four or five hours, and for about half an hour, or possibly more, had been steadily looking at a lamp (a habit of mine when thinking); I then got up, leaving the lamp lit, and went out on my way to my bed-room as mentioned above. On going out of the room my shadow was thrown by the lamp on the wall just to the right of the door. The passages were entirely dark, and it was not until I entered the room used as a study, that the faint light coming through the window and falling on the same spot of the retina that was previously occupied by the image of the dark doorway, stimulated the after-image.

I may say that my health was of the best, but that I had been smoking heavily for a few days previously, and the fact had begun to force itself upon me.

I would especially remark upon the apparent brightness of the apparition. I had never seen an after-image so bright. On going back to the room where the lamp was, I proved that the appearance of the shadow thrown as I went out of the room corresponded with that of the image seen, minus of course the features and colour, which had been supplied by the imagination.

In speaking of optical phenomena, I would say that an easy way of showing that the colours seen in the colour-top are due to lack of accommodation, is by taking a piece of red paper or cloth, and turning the top till the inner or outer line matches it exactly. Then, without moving or changing the speed of the top, place before the eye a convex glass. The colour on the top will disappear, but that of the cloth will of course remain. Similar experiments to those observed with the top can be observed by drawing dark lines on a piece of glass, and waving dark and white paper behind them.

A Remarkable Flight of Birds.

The forms of birds flying at a great height and crossing the solar disc, as described by Mr. Bray in your issue of August 29, have been rather frequently seen here during the spring and autumn months, and the writer has always attributed such flights to migrating birds on passage. They have usually been noticed while observing the image of the sun projected on a card screen from the eyepiece of a small equatorial telescope; occasionally, however, they have attracted attention at night also, crossing the disc of the moon, upon which their forms are very clearly defined, and with careful focussing (which is very nearly the same as for parallel rays) it has almost been possible to identify the species from the shape of the wings and manner of flight; birds of the swallow tribe, in particular, have been clearly distinguished, and others resembling the thrush, possibly redwings or fieldfares, have been noticed. The direction of flight, according to the writer's experience, is nearly always towards the south in August and September, and the reverse in April.

On August 31, a continuous watch was kept on the moon from 8.50 to 9.35 P.M., using a power of 80 diameters on a reflector of 10 feet focus. Only eight birds were seen, however, four of them slowly crossing from north to south, the other two from west to east (nearly). They were evidently very distant. An estimate of the change of focus required for the apparently nearest bird gave ·15 inch. This would imply a distance of 7000 feet from the telescope, and the moon's altitude being about 14° the vertical height of this bird would be 7900 × sine 14° = 1000 feet (about). Some of the birds, judging from their apparent size, must have been two or three times more distant, and therefore higher in the same proportion.

It would be very interesting to obtain systematic observations of such flights of birds from various localities during the migrating seasons. Possessors of telescopes would find these observations a good exercise in that kind of patience or endurance which is so necessary in observing, for instance, a so-called meteor shower at its maximum!

The writer would be glad to receive notes on the subject from those of your readers who may care to watch for birds during the autumn. Estimates of the angle subtended by the spread wings would perhaps give the most reliable means of ascertaining the height of the birds, and their direction of flight can easily be obtained by reference to the diurnal motion of the sun or moon. It is hoped that by collecting data of this kind some new facts may be learned regarding the mysterious habits of our bird visitors.

J. Evershed.

Kenley, Surrey.

THE WOBURN EXPERIMENTAL FRUIT FARM.

On June 12 last a small party of those interested in agriculture and horticulture, including Mr. Herbert Gardner, Sir John Thorold, Prof. Armstrong, Prof. Warington, Dr. Voelcker, Mr. Charles Howard, Mr

Carruthers, Mr. George Murray, and others, visited Woburn to make the first formal inspection of an institution which, under the above somewhat unpretentious title, has been established by the joint action of the Duke of Bedford and Mr. Spencer Pickering, F.R.S., in order to supply what has hitherto been a great national want.

The object of this institution is to provide an experimental station where all matters connected with horticulture, and especially with the culture of hardy fruits, may be investigated both from the scientific and practical point of view.

The origin of such an enterprise is always a matter of some interest, and it becomes all the more so in after years, when, too often, the details of its conception and evolution are irretrievably lost. In the present instance we may trace the origin to an accident in a chemical laboratory. It was owing to such an accident some years ago that Mr. Pickering, whose work in physical chemistry is well known, was driven to seek health in a partial existence in the country. Not having the means, however, to procure this in the orthodox manner without abandoning his scientific work, he resorted to the somewhat unusual means of getting air and exercise by becoming an agricultural labourer at Rothamsted. From an agricultural labourer to a small farmer and landowner the steps were not so tedious as is generally the case, and for some few years past Mr. Pickering has turned his attention, after the manner of many landowners, to horticulture and practical fructiculture. To any one of a scientific turn of mind the unsatisfactory basis on which the culture of fruit depends cannot fail to be apparent. Its present condition is little better than that of horticulture some fifty years ago. It rests mainly on the hard-earned and often one-sided experience of practical men, gardeners, for the most part, or nurserymen.

But the pressure of business will rarely allow a nurseryman to indulge in anything approaching to systematic research, and even when he does obtain any important results, they are liable to be looked on askance, as being possibly tinctured by mercenary considerations. Moreover, even amongst the highest practical authorities there is hardly a single point in the cultivation of fruit on which unanimity of opinion prevails; indeed, on some of even the most elementary processes there seem to be as many opinions as there are so-called authorities.

The desirability of having some station where such matters might be patiently investigated, and from which results might issue free from any taint of commercial expediency, was evident to Mr. Pickering, and not having himself the capital or land necessary for such an undertaking, he applied for assistance to a former college friend, the Duke of Bedford. The Dukes of Bedford have during generations past identified themselves with the progress of agriculture and horticulture, the present holder of the title showing no tendency to be eclipsed by his predecessors in these matters. As was probable, such a scheme met with the hearty approval of the Duke, and the result was the establishment of the present institution, conducted jointly by himself and Mr. Pickering.

The fruit farm is on the Duke's land near Ridgmount Station, and almost adjoins the land which is given up to the use of the Royal Agricultural Society as an experimental agricultural station. About twenty acres have been devoted to the purpose, and of this some fifteen have already been planted.

Everything at present justifies the anticipation that this station will be conducted in the liberal and thorough-going manner which alone can produce results capable of commanding the confidence of horticulturists, and the energy with which the work has been commenced indicates that no time will be lost in obtaining trustworthy results. It is but twelve months since the field was bearing a crop of roots and weeds (especially the latter), yet in spite of the adverse season, the ground has been thoroughly cleaned, roads, hedges, and fences have been made, a house built on it, and over 500 experimental plots have been planted; also an extensive nursery has been planted, as well as collections of various ornamental and useful trees and shrubs. A fine crop of eighty different varieties of strawberries has been already gathered. With such work accomplished, it is scarcely necessary to say that an able manager is resident on the farm. The present manager, Mr. L. Castle, is a man whose experience and knowledge will command the confidence of practical horticulturists.

It is only possible here to indicate briefly the character of some of the experiments instituted. Besides strawberries—the investigation of which will embrace not only the respective merits of different varieties, but also the comparative values of the varieties at different ages, and the effects of certain manures on the crop—apples have been selected for the majority of the experiments already begun. Sixty different experiments are arranged to test different methods of planting, of root and branch treatment, and different manurial treatment, each experiment being made on eighteen trees, six of each of three varieties, all of the same age, and all raised on the same stock. These trees are all dwarf trees, and certain of the experiments are repeated with standard trees on the free-growing stock, and also with other dwarf trees of a fourth variety. Thirty-eight plots have been devoted to ascertaining the influence of different methods of training on the quantity and quality of the crop, and a collection of about 120 good varieties of apples has been made, each variety being grown on different stocks, and subjected in each case to different methods of treatment. This collection of apples is also so arranged that it may be utilised for the investigation of insecticides, without destroying the value of the results as regards the comparison of the different varieties. A smaller but interesting collection of apples of Scotch, Irish, and foreign origin has also been made. The numerous shelter hedges which have been planted are also of considerable interest, since, from an economical point of view, they also are experimental. They are composed of different varieties of nuts, plums, damsons, crabs, quince, medlars, and berberries.

Other experiments of greater scientific interest than the above are, we understand, either in progress or in contemplation; amongst these may be mentioned the influence of different stocks on the scion, and the great question of the effects of self- or cross-fertilisation. Such experiments, however, necessitate the lapse of a considerable amount of time before they can be said even to have been started, if they are to be started on a really satisfactory basis.

Those who are familiar with Mr. Pickering's chemical work will not fear that sufficient attention to minute details will be absent from the present undertaking. As instances of the thoroughness with which small questions are being examined, we may mention experiments on the relative merits of different arrangements of the same number of trees in a given area, and of the different direction in which the rows run as regards the points of the compass. Or, again, experiments on the influence of the nature, position, and inclination of the cut given in pruning a branch, and also the improvements which are being devised in methods of measuring the evaporating power of the air.

But it is very noteworthy that the strictly practical and economical aspects of horticulture will receive more attention than is usually the case at experimental stations. Six demonstration plots of a quarter of an acre each have been planted to illustrate how land may be most advantageously cropped by farmers, growers, and cottagers respectively. The initial cost of each of these plots is known, and an accurate account of the incoming and outgoing connected with each will be kept. In the nursery,

to which allusion has already been made, trees and bushes are being raised for distribution amongst the Duke's tenantry. We are pleased, however, to find that these practical steps for the promotion of fructiculture do not originate in any extravagant notions of the all-saving powers of fruit-growing to remedy the present agricultural distress. Much harm has been done in this country by the special pleading of those who are faddists on the subject, and who advocate their fad by holding up to view all the notable cases of success, and all the possible advantages to be gained, while they keep in the background all the difficulties and dangers, minimise the costs of planting, and hide the numerous cases of failure. No one can question the fact that fruit-growing in England is a profitable occupation when properly conducted under favourable conditions of soil, climate, and distance from market: nor can it be doubted that a certain proportion (perhaps 5 or 10 per cent.) of those who are now ordinary farmers could become fruit farmers with great advantage to themselves, and it must also be admitted that the distribution of some knowledge of fruit growing over the country generally would render the thousands of orchards attached to homesteads a source of small, or often substantial, profit to the holders, instead of being, as they are at present, a mere waste of land and money: but to imagine that every farmer can become a fruit grower is as absurd as imagining that every farmer could become a horse breeder. Even if such a metamorphosis were possible it would be suicidal; yet it should be pointed out that the fruit market in England is an exceptionally expansible one, and that prices of hard fruits would probably be but little affected even if the supply were doubled: the rapidly increasing importation of apples, which has now reached 3,000,000 bushels a year, has had no effect whatever on the market price of the fruit. These might have been grown in England just as well as abroad, for with a proper selection of varieties England need never fear a competition with foreign-grown apples.

It is certainly a fallacy to suppose that it is only in a few exceptionally favoured districts that fruit can be profitably grown: the appearance of the trees and the abundant crop of strawberries at the Woburn Experimental Fruit Farm are sufficient to demonstrate that a field of ordinary arable land of average fertility, with nothing to recommend it for fruit-growing beyond having a gentle slope to the south-west, and with a reputation amongst farmers of being the most unmanageable in the district, may be rendered highly suited for the production of fruit. To produce such results, however, right methods of procedure are, of course, essential, and nothing could be more striking than the difference between the bulk of the apple-trees at the farm, and those growing on two plots where the planting and subsequent treatment were such as is usually adopted by farmers: the ground where these trees were had, indeed, been properly trenched and cleaned once, but the trees had been carelessly planted, the branches had not been cut back, and the weeds had been subsequently allowed to grow: the result was that along the branches there were only a few half-dead leaves of not more than one-fifth of the proper size, and it would have required a trained horticulturist to have recognised that these trees were of the same variety as those which had been properly tended.

We were also much struck by the evidence which the results at the farm afforded of the hardiness of English fruit trees. No season could have been more trying to recently planted trees than that just experienced. A very wet autumn, during which the heavy soil of the farm was unworkable, was followed by a winter of almost unprecedented severity, and this, in its turn, by a still more trying period of drought. Yet, with the exception of the young stocks and a few strawberry plants, the mortality amongst the thousands of trees and bushes brought on to the ground in the autumn, was confined to about six individuals and half of these were killed through the improper method purposely adopted in planting them.

All readers of NATURE will wish success to an enterprise so well begun and so liberally conducted, which is clearly destined to afford results of high economic and scientific value.

THE REVISION OF THE "BRITISH PHARMACOPŒIA."

THE last edition of the "British Pharmacopœia" was issued in 1885, and though a thin volume of "Additions" was published by the General Medical Council in 1890, the progress of science and the requirements of medical practice have rendered necessary a complete revision of the official handbook. The work has accordingly been entrusted to a Committee of the Council, consisting of Sir Richard Quain, F.R.S., Chairman, the only remaining member of the Committee of 1885; Sir Dyce Duckworth and Mr. Carter, of London; Dr. Leech, of Manchester; Dr. Batty Tuke, of Edinburgh; Dr. Donald MacAlister, of Cambridge; Dr. McVail, of Glasgow; and Dr. Atthill and Dr. Moore, of Dublin. Dr. Nestor Tirard, of King's College, London, has been appointed secretary to the Committee, and Prof. Attfield, F.R.S., of the Pharmaceutical Society of Great Britain, general editor. On questions of chemistry, Dr. T. E. Thorpe, F.R.S., Principal of the Government Laboratory at Somerset House, with Prof. Emerson Reynolds, F.R.S., of Dublin, and Prof. Tilden, F.R.S., of the Royal College of Science, have been invited to act as scientific referees. Mr. W. T. Thiselton-Dyer, F.R.S., Director of the Royal Botanic Gardens, Kew, and Mr. Holmes, Curator of the Pharmaceutical Society's Museum, have received a similar invitation as regards botanical questions. The rapid growth of experimental pharmacology has, moreover, rendered it desirable to enlist expert assistance in regard to the physiological properties and actions of new remedies, and accordingly difficult questions of this nature will be referred to Dr. Lauder Brunton, of London, Prof. Fraser, of Edinburgh, and Prof. W. G. Smith, of Dublin. Lastly, on matters of pharmacy, the Pharmaceutical Society have been asked to give their valuable aid, and have promptly formed a strong committee of practical experts. To this committee many questions as to the compounding and preparation of drugs will doubtless have to be referred.

A circular inviting suggestions for the improvement of the "Pharmacopœia" has been addressed to the several universities and medical licensing corporations of the United Kingdom, and from the majority of these careful and elaborate replies have been received. They contain numerous proposals for the omission of doubtful or obsolete preparations, for the incorporation of new drugs that have come into practical use since 1885, and for the simplification and correction of the text in general.

In response to requests transmitted through the Privy Council to the medical authorities of the colonies and India, a very large body of materials, submitted with the object of adapting the "Pharmacopœia" to the requirements of the empire at large, have reached the editing committee. These open up a multitude of somewhat difficult questions; for though the "Pharmacopœia" is by law recognised as the official standard of reference at home, it has not the same legal sanction outside the British Isles. While therefore it is possible that something may be done as regards the recognition of important natural drugs used in Indian or colonial practice, it is highly probable that these may have to be relegated to a special appendix. The desire to go as far as may legally be practicable in making the "Pharmacopœia" an im-

perial one is, however, highly laudable, and should be encouraged with a view to the unification of British medical science. It is further announced that a long-deferred step is about to be taken by the introduction of the metric system into the body of the work. In the present edition the centimetres and grammes of science appear modestly in the supplementary pages dealing with volumetric processes, and then only as an alternative to grains and "grain-measures." We understand that in the new revision centimetres and grammes will be made official in all the monographs of the text, side by side with the still legalised grains and ounces, minims and drachms. This change will bring the British handbook into line with the official dispensatories of all other civilised States, and should tend to hasten the time when the international system of metric weights and measures shall acquire full legal authority in this country.

It thus appears that the Medical Council's Committee have undertaken the task of revision with an adequate sense of their responsibility. They have in the suggestions of the medical authorities at home and abroad, and in the useful digests of the literature of pharmacy, prepared from year to year by their reporter, Prof. Attfield, ample materials whereon to base their deliberations. As a body of physicians representing the supreme council of the profession, they are eminently qualified to judge as to the requirements of practical medicine and clinical therapeutics. Where their domain borders on that of the specialist in chemistry, botany, pharmacy, or physiological pharmacology, they propose to have recourse to the most skilled representatives of these branches of science. The result of their labours, thus conceived and carried out, will be awaited with interest not only by practitioners of medicine and pharmacy, and by manufacturing chemists, but by all who have sympathy with the application of science to human needs.

THE FIRST MERIDIAN.

At the recent Geographical Congress in London, the question of the first meridian was discussed with particular interest.

It was proposed that the first meridian should not be established officially, but should merely be settled with a view to producing an international map to the scale of millionths. M. A. de Lapparent has written an article in *La Nature* on the subject, of which the following is an analysis: it is a noteworthy occurrence that a Frenchman should have taken up the subject with such interest, for the French has hitherto been the only nation to reject the Greenwich meridian. In the preliminary discussions they have brought upon themselves many reproaches for hindering a scientific work the use of which every one had recognised, while they themselves had no principle to bring forward to support their objections. The matter has been much discussed amongst them, and at the Geographical Society of Paris, by a special commission, it was decided that the map should be accepted. It was considered best that France should not be the only country to refuse the project: nevertheless, it was decided to insist on the metric system being used, for here a principle was involved.

On this subject M. de Lapparent writes as follows:

"Thus, true to its habit of fighting for its views, France has again showed itself champion of the metric system, offering to make, for the scientific and rational interest, a sacrifice of national self-love. It would be impossible for it to capitulate on the question of the system, for here a principle is concerned; but the choice of a meridian, depending on no logical consideration, could be more easily granted. Evidently the proposed map, if ever produced was to be arranged so as to be a help to already existing aps, the latter being in great majority on the meridian of Greenwich; by wishing to impose the meridian of Paris which would not have been a success, it would have caused greater trouble than the contrary case. Henry IV. estimated that Paris was worth a mass; the French delegates, however, said on their side that the concession of a meridian, for a special and determined work, was quite worth the agreement which was expected to be established in view of the adoption, for the same purpose, of the metric system."

Many of our own countrymen have regretted that the public spirit prevented the system being used officially in Britain.

However, the acceptance of the Greenwich meridian well deserved a recompense, and the vote was unanimously carried that the metric system should be used for the map.

It is worth observing that the subject was discussed with remarkably few disagreements, considering that the congress was international. This seems to show that the time is fast approaching when national prejudices will be done away with if they support illogical theories; if principles are involved, it is right they should be adhered to, but they should not be allowed to hinder an enterprise profitable, perhaps, to all humanity.

NOTES.

The *Times* of yesterday published a telegram, dated September 17, from Sandefiord, Norway, received through Reuter's Agency, stating that advices received at Sandefiord from the Danish trading station of Angmagsalik, on the east coast of Greenland, state that towards the end of July a three-masted ship, with a short foremast, was seen by Eskimos on two occasions firmly embedded in drift ice. On the first occasion the ship was observed off Sermiligak, 65° 45′ lat. N., 36° 15′ long. W.; and the second time off Sermelik, 65° 20′ lat. N., 38° long. W. It is believed tha the vessel was Dr. Nansen's *Fram*, and that she was on her return journey. In any case, however, no positive news of the exploring vessel is expected to arrive until next year.

On Wednesday, Sept. 11, a Reuter telegram announced that the steam yacht *Windward*, which took out the Jackson-Harmsworth Polar Expedition, had arrived at Vardo, and on Thursday another telegram, through the same Company's agency, stated that the expedition, after leaving Archangel, passed the winter on Franz Joseph Land, from which place a start was made in the middle of July. The crew appear to have suffered severely from scurvy, and all the members of it are more or less weakened by the malady. Three of the men succumbed, and two others were removed to the hospital at Vardo.

The *Standard* states that the excavations that are being carried out by the Greek Archæological Society on the site of ancient Eleusis, a few miles from Athens, have just yielded some results of exceptional importance. In a very ancient and well-preserved tomb, there have been found, in addition to the skeleton of a woman, a number of articles, including earrings of fine gold, silver, and bronze, several finger rings, sixty-eight small vases of various shapes in terra-cotta, two tripods, three Egyptian scarabæi, and a small statuette of the goddess Isis in porcelain. These discoveries leave no doubt of the fact that the celebrated mysteries of Eleusis were of Egyptian origin, and were borrowed from the religious rites of the ancient Egyptians. These important relics have been deposited in the National Museum.

A Reuter's telegram of September 11, from Berne, reported the fall of a huge mass of ice from the Altels Glacier upon the hamlet of Spitalmatte, in the Upper Gemmi Pass, causing the death of at least ten persons, and the loss of, it is estimated, two hundred head of cattle. A stretch of land nearly two miles

in length has been overwhelmed, and the pass has been partially blocked.

THE death is recorded of Dr. L. Galassi, Professor of Medical Pathology in the University of Rome; Dr. Friedrich Miescher, sometime Professor of Physiological Chemistry, and Dr. von Sury, Professor of Forensic Medicine in the University of Basel.

DR. RUFFER is, we are sorry to learn, suffering from an attack of diphtheritic paralysis, and will not, in consequence, be able to deliver his intended course of lectures at the British Institute of Preventive Medicine, or, indeed, do any work for some time to come.

THE following lectures will be delivered at the Royal College of Physicians during the coming year: The Goulstonian Course by Dr. Patrick Manson; the Lumleian Lectures by Sir Dyce Duckworth; the Croonian Lectures by Dr. George Oliver; and the Bradshaw Lecture by Dr. Bradbury. The Croonian lecturer for 1897 is Dr. Greenfield.

THE Berlin Academy of Sciences will award the Steiner prizes, of the respective value of 4000 and 2000 marks, for papers in continuation of J. Steiner's work on curved surfaces. The essays must be submitted to the Academy before the end of 1899.

AMONG a number of plumassier's bird-skins, said to have been brought from the foot of the Charles Louis mountains in New Guinea, has been found the skin of a most remarkable new Bird of Paradise of the genus *Astrapia*, conspicuous for its crimson gorget and black-and-white tail. This specimen, which has been secured for the Tring Museum, has just been described by Mr. Walter Rothschild as *Astrapia splendidissima*.

A NEW part of the quarto *Transactions* of the Zoological Society, which will be issued on October 1, will contain an important memoir on the Dinornithidæ, by Prof. T. Jeffery Parker. The author enters at length upon the osteology, classification and phylogeny of these extinct birds, giving special attention to their cranial characters. Prof. Parker is inclined to associate the Moas with the Kiwis (Apterygidæ), rather than with any other existing family of the class of birds.

WITH the new number that has just been issued, the publication of that valuable American periodical *Insect Life* comes to an end. The cessation takes place, we are told, for administrative reasons. Happily, the good work which it accomplished will be continued in two series of bulletins from the Division of Entomology of the U.S. Department of Agriculture. A new series of general bulletins will be begun, and will contain short reports on special observations, and the miscellaneous practical and economic results of the work of the division, and in directions of general interest. This first series will be sent to all the present readers of *Insect Life* who desire them. The second series of bulletins, published at rarer intervals, will publish the results of the purely scientific work of the members of the office force, and will consist largely of longer or shorter monographic papers on groups of North American insects. This series will be distributed only to libraries and to working entomologists. The publication of the divisional series of circulars of information upon especially injurious insects, of farmers' bulletins upon special entomological topics (principally methods of treatment), and of occasional special reports will be continued.

THE Third Report of the Royal Commission appointed to inquire what light-houses and light-vessels it is desirable to connect with the telegraphic system of the United Kingdom by electrical communication, stated that the value of the warning conveyed to passing vessels by the display of storm signals, on the occasion of the approach of heavy gales, could scarcely be overestimated, and recommended that the light-houses on the most prominent points of the coast of the United Kingdom, with which electrical communication exists, should be made storm-warning stations. In compliance with this recommendation the Meteorological Council have now made arrangements for the supply of storm-warning telegrams to twenty-five prominent headlands on the coast, for the benefit of passing vessels, in addition to the telegrams at present forwarded to ports and harbours, which are intended more particularly for the use of vessels leaving the places at which the signals are hoisted. The signals used are canvas cones, with point upwards or downwards, to signify whether northerly or easterly, or southerly or westerly gales are expected, and are practically the same as those originally adopted in 1860 by Admiral FitzRoy, then chief of the Meteorological Department of the Board of Trade. The light-house authorities have readily assisted in carrying out the recommendation of the Royal Commission, by allowing their light-keepers to undertake the management of the signals.

WE have received a volume of meteorological observations made at Rousdon Observatory during the year 1894, under the superintendence of Mr. Cuthbert E. Peek. This observatory is situated a short distance within the eastern boundary of Devonshire, in close proximity to the cliff, at an elevation of 516 feet above mean sea level, and forms an important station of the Royal Meteorological Society. In addition to very complete meteorological observations, experiments of various kinds are carried on, in connection with evaporation, agriculture, &c. Mr. Peek remarks that, from an agricultural point of view, the year 1894 may be briefly summarised as a year of plenty, but with prices too low to pay for the cost of production. Since 1883, a daily comparison of the weather experienced at this observatory with that predicted for the district in the forecasts issued by the Meteorological Office has been made. The published daily weather reports were received the day following the date of issue, and the forecasts contained in them were therefore not seen until after the actual weather experienced had been recorded. The results have proved of much interest; for the year 1894, ninety-three per cent of the forecasts for wind and for weather, separately compared, were found to be trustworthy. A table of comparisons for the years 1884–94 shows that the percentage of successful forecasts has improved year by year.

THE preparation of artificial human milk has from time to time occupied the attention of investigators, but so far, according to Dr. Backhaus, no satisfactory substitute has been produced in the place of human milk. Dr. Backhaus has, however, quite recently endeavoured to supply this deficiency, and stimulated by Kehrer's method he has succeeded in producing so-called artificial human milk. The milk is carefully collected with the usual hygienic precautions of cleanliness, &c., and then submitted to fermentation by means of rennet, in the course of which a relatively rich milk serum is procured containing albumen and milk sugar. This serum is carefully sterilised, and by the addition of cream a material is produced which closely resembles human milk, which may be varied in composition according to the age or particular requirements of the individual. Since, however, our knowledge of the properties possessed by the natural fluids of the body has been recently extended in so remarkable a manner, the subject of artificial milks has become invested with new considerations, which a few years ago were not even suspected. In the course of his paper Dr. Backhaus points out that the sterilisation of milk should, if possible, be carried out on the large scale in dairies before distribution, that in this way better apparatus being to hand, more cleanly besides more effectual results will be obtained than when it is left in the hands of private individuals. As demonstrating the importance of freeing the milk from impurities before use, Dr. Backhaus mentions that

the city of Berlin alone consumes daily with its milk 300 cwt. of cow dung!

Although the extension of geological research into distant parts of the earth has shown that the divisions of time originally made in Europe are not always applicable to other areas, yet it is possible that the greatest geological division-lines that are recognised may represent world-wide periods of rapid change. Such is the view expressed by Prof. Le Conte in a paper on "Critical Periods in the History of the Earth," published by the University of California. He considers that in the evolution of the earth there must have been now and again, amid many smaller local changes, readjustments of the crust affecting the whole earth, with something approaching simultaneity. Such universal changes must be used to mark out the primary divisions of time: they are marked by widespread unconformities and the birth of great mountain-ranges, and as consequences of these changes in physical geology there follow remingling of faunas, the extinction of many types, the more rapid evolution of new forms, and the origin of new dominant classes. We thus have an alternation of short "critical" periods of extensive change and long periods of gradual change, the former marking the commencement of the great time-divisions of the earth's history. Four such critical periods can, in Prof. Le Conte's opinion, be recognised—the pre-Cambrian, the post-Palæozoic, the post-Cretaceous, and the Glacial. Comparing these with one another, he finds progressive change in their character; each one is shorter in duration than the previous one, and involves greater climatic changes and increased faunal effects from the introduction of new dominant types.

Dr. Gerhard Schott has published some interesting maps concerning the present conditions of sail navigation, which are appended to his paper on the subject appearing in the *Zeitschrift der Gesellschaft für Erdkunde*. They are chiefly compiled from log-books examined at the Deutsche Seewarte, Hamburg. The two main lines of voyages for German sailors are the "saltpetre trips" to the west coast of South America, and the "rice trips" to India and the Straits Settlements. A map divided into zones of equal travelling times from the Lizard shows the remarkable fact that the mouth of the Congo is one of the most difficult parts to reach in a sailing vessel. The Cape and Patagonia can be reached in the same time. The southern Indian Ocean forms a kind of racecourse along which the vessels speed to Australia in the same time as it would take to reach Zanzibar. Adelaide can be reached in ninety days, and so can Chile. New York, which requires forty days, is in that respect as distant as Panama, and is one of the most inaccessible ports for a sailing vessel, especially in the winter. The return is easier, and can be accomplished in twenty-five days, whereas the return from Panama takes sixty. The return from Australia is equally lengthy round the Cape as by Cape Horn, and the latter route is now preferred owing to the notoriously dangerous character of Cape Agulhas. Needless to say, the Suez Canal is quite useless for sailing vessels. Even apart from the fact that the Red Sea is most difficult to navigate, the canal dues exclude vessels whose vitality lies solely in the cheap freights they can offer in competition with steamers. With the modern construction of sailing vessels, which are built almost exclusively of iron and steel, the only enemies seriously feared are fogs, icebergs, and dead calms, to which we must add, in the much-frequented ocean highways of the northern Atlantic, the fast mail steamer. The average skipper does not mind a storm, but rather welcomes it, as it makes him go all the faster.

The *Journal of the Franklin Institute* states that the recent trials of electric locomotives at Nantasket Beach, near Boston, and at Baltimore, have so satisfactorily demonstrated the superiority of this class of motor over the steam locomotive for short hauls, that it is now very generally admitted that the near future will witness a very extensive application of the new form of motive power for short branch lines, tunnel haulage, &c. At the Nantasket Beach trials, it is stated that a speed exceeding sixty miles an hour was attained, and at Baltimore the test of the electric locomotive designed to draw trains through the tunnel, 7430 feet long, in that city, was highly successful. A maximum speed of fifty miles an hour is to be developed, and it is guaranteed that the locomotive will pull 1200 tons at a speed of thirty miles an hour. The system has been in practical and regular operation on the Nantasket Beach Railway since the end of June last.

According to the *Engineer*, a French physicist, M. Denayrouze claims to have discovered a means of increasing the illuminating power of gas about fifteen times. In his lamp M. Denayrouze employs a spherical-shaped metallic body, and a mantle capable of being raised to incandescence. In the body of the lamp is fixed a tiny motor, which works a ventilator, and which receives current from a couple of small accumulators. The electrical energy required is said to be only $\frac{1}{4}$ volt and $\frac{1}{15}$ of an ampere, and to be sufficient to force a current of air through the mantle and to cause the gas to burn with remarkable brilliancy. The burner is said to consume seven litres of gas per carcel, and lamps have been made having an illuminating power of 800-candle power.

Speaking of some experiments in marching, which have recently been carried out at the request of the German War Office, by some students of medicine of the Friedrich Wilhelm Institute in Berlin, who for the purpose wore the regulation uniforms and carried the full field service equipments, the *British Medical Journal* says:—"The marches performed varied from 22 to 33 miles, and were executed in all kinds of weather. The weights or loads carried varied from 48 to 68 lbs., the full service equipment of the German infantry soldier averaging 70 lbs. That of our own infantry does not usually exceed 60 lbs. The conclusions arrived at by the medical officers in charge of the experimental observations were practically as follows: When the load is not excessive and does not exceed 48 lbs. a march of twenty-five miles executed in cool weather (60 F.) is readily performed, and has no deleterious effects upon the man, even if continued for some days consecutively. With a mean temperature of 70° F. a similar load carried the same distance has a considerable temporary effect upon the organism, necessitating a rest of at least ten hours in the twenty-four. A load of 68 lbs. could not be carried twenty-five miles without inducing grave physiological disturbance, necessitating a full day's rest on the following day. This weight was not readily carried day by day without derangement of health over greater distance than fifteen miles. A weight of 60 lbs. was the maximum weight which could be carried on consecutive days for twenty-five miles by a man weighing 11 stone during ordinary summer weather consistently with health. It is not stated whether the men by whom these experiments were made were picked individuals, or what was their dietary."

The current number of *The Leisure Hour* contains an interesting article by E. Whymper, on some high mountain observatories, accompanied by illustrations and short accounts of the difficulties experienced and the results attained. The observatories described are:—Mount Washington, in New Hampshire, U.S.A., 6286 feet high; it was established in 1870, but is now closed. Pike's Peak, in Colorado, 14,134 feet high, was erected in 1873, and closed in 1888. This station was celebrated for its electrical storms. The most elevated station is on the top of the Misti, near Arequipa, in Peru. This is 19,200 feet above the sea, but notwithstanding its great elevation, the ascent is comparatively easy. About twelve miles to the north

... is a mountain called Chachani, about 20,000 feet high; an observatory was established just below the snow-line, at the height of 10,050 feet, in the years 1892–3, but is now abandoned. The article contains a graphic account of the difficulties of establishing two observatories on Mont Blanc, one at 14,320 feet, and the other on the summit, at 15,780 feet, by M. Vallot and M. Janssen, respectively. The meteorograph for the summit of Mont Blanc has been constructed by M. Richard at a cost of £750, and the clockwork is calculated to remain in action for eight months.

USEFUL and practical publications continue to issue from the various botanical experiment stations in the United States. We have on our table the following: From Kansas State Agricultural College, *Bulletin* No. 50, comprising a list of Kansas weeds, with descriptions, and figures of the seedling forms; from Cornell University, an essay, by Mr. G. F. Atkinson, on "Damping Off," containing a description, with figures, of the various parasitic fungi which accompany this phenomenon, including a new species, *Volutella leucotricha*; and "Studies in Artificial Cultures of Entomogenous Fungi," by Mr. R. H. Pettit, also illustrated by plates.

THE Report of the Botanical Exchange Club of the British Isles for the current year is issued, with a list of Desiderata. The main portion of the very useful work done by this Association rests with two or three individuals. This work would be greatly promoted by the addition of a few new subscribers, who should address themselves to Mr. Charles Bailey, College Road, Whalley Range, Manchester.

THE following colonial botanical publications have reached us:—The *Bulletin* of miscellaneous information of the Royal Botanic Gardens, Trinidad, for July, containing a number of notes on native and cultivated plants in the colony, by Mr. J. H. Hart; *Botany Bulletin*, No. 10, of the Department of Agriculture, Brisbane, consisting of contributions to the Queensland flora, by Mr. F. M. Bailey; *Proceedings* of the Royal Society of Queensland, vol. xi. pt. 1, with the annual address of the President, Mr. R. L. Jack, on "The Higher Utilitarianism."

MESSRS. G. PHILIP AND SON have reprinted for Dr. Mill the paper on "The English Lakes," which, under the title of "On the Bathymetrical Survey of the English Lakes," the author contributed to the July and August numbers of the *Geographical Journal*. The book is nicely got up, and is illustrated by numerous photographic views, maps, and diagrams.

A NEW edition—the third—of Clowes and Coleman's "Quantitative Chemical Analysis" has been sent to us by Messrs. J. and A. Churchill. The work has undergone certain changes since the publication of the second edition, the matter having been increased, the text revised, and some new figures added.

THE September part of *Science Progress* contains the following articles:—"Progress in the Study of the Ancient Sediments," by J. E. Marr; "On the Respiratory Function of Stomata," by F. Frost Blackman; "The Zoological Position of the Trilobites," by H. M. Bernard; "Some Metasomatic Changes in Limestones," by A. Harker; and "The Decomposition Products of Proteids," by Dr. T. Gregor Brodie.

THE series of small books, entitled "Encyclopédie Scientifique des Aide-Mémoire," which is being brought out conjointly by Messrs. Gauthier-Villars and G. Masson, of Paris, has had another volume added to it by the publication of "Cubature des Terrasses et Mouvement des Terres," by G. Dariès.

THE paper "On the Cost of Warships," which was read by Dr. Elgar at this year's summer meeting of the Institution of Naval Architects, has been issued in pamphlet form by the Institution. The pamphlet also contains a report of the discussion on the paper which took place at the meeting.

WE have received the *Memoirs and Proceedings of the Manchester Literary and Philosophical Society*, fourth series, vol. ix., No. 3, 4, and 5, and the *Journal of the Asiatic Society of Bengal*, vol. lxiv., part 2, No. 2.

MR. R. W. PAUL, of Hatton Garden, has sent to us advance sheets of his new catalogue of electrical testing and measuring instruments. Many of the instruments are figured.

THE University Correspondence College has issued its Intermediate Arts Guide, No. x., with the papers set at London University, July 1895, and articles on the special subjects for 1896, and its London Inter. Science and Prel. Sci. Guide No. vii., with the papers set at London University, July 1895.

THE August numbers of the *Journal of the Royal Microscopical Society* and of *Clinical Sketches* have reached us; also part vi. of the *Katalog der Bibliothek der Kaiserlichen Leopoldino-Carolinischen Deutschen Akademie der Naturforscher*, Halle; and Messrs. Friedlander and Sohn, Berlin, have sent us No. x. to xiv. of *Naturae Novitates*.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Miss E. S. Cooper; a Smith's Dwarf Lemur (*Microcebus smithi*) from Madagascar, presented by Miss Ruby Woolcott; a Yellow-fronted Amazon (*Chrysotis ochrocephala*) from Guiana, presented by Mr. W. Page; a Beautiful Grass Finch (*Poephila mirabilis*, ♂) from Australia, presented by Mr. Gerard O'Shea; a Brazilian Tortoise (*Testudo tabulata*) from Brazil, deposited; three Boas (*Boa constrictor*) from Brazil, purchased; a Wapiti Deer (*Cervus canadensis*, ♂), two Triangular-spotted Pigeons (*Columba guinea*), a Spotted Pigeon (*Columba maculosa*), two Crested Pigeons (*Ocyphaps lophotes*), two Half-collared Doves (*Turtur semitorquatus*), two Vinaceous Doves (*Turtur vinaceus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF MARS.—In connection with the recent discussion as to the presence or absence of the bands of water vapour in the spectrum of Mars, Dr. Janssen has published further particulars of the observations made by him in 1867 (*Comptes rendus*, July 29). He points out that even with the quantity of vapour in our own atmosphere, the bands would be all but invisible to an observer on Mars if the solar light were reflected normally from the earth's surface, and since the general conditions of the planet point to its atmosphere being less important than our own, it is easy to understand that the detection of the bands is a very delicate observation. To reduce the absorptive effect of the terrestrial atmosphere, observations should be made at a high altitude, and the use of the lunar spectrum as a term of comparison is also important. As to the apparatus required, Dr. Janssen does not consider large telescopes indispensable, as even with them the telluric bands can only be observed in their totality. Previous to observing the spectrum of Mars, Dr. Janssen had been engaged in an extensive study of the spectrum of water vapour as exhibited by a tube 37 metres in length. The observations of Mars were made on May 12–15, 1867, from a station on Mount Etna at an altitude of nearly 3000 metres; at meridian passage the altitude of the planet was 72°, and at sunset, when the observations were commenced, it was still more than 60° above the horizon, while the moon was a little lower. The cold was excessive during the nights of observation, and the quantity of vapour contained in the atmosphere overlying the place of observation would not be able to give indications of the telluric groups near C and D, according to the experiments with the long tube. Under these highly favourable conditions, Dr. Janssen found feeble but certain indications of the groups at C and D, and he is confident that future researches will justify the conclusion at which he arrived.

APPARATUS TO ILLUSTRATE DOPPLER'S PRINCIPLE.—The movement of the lines in a spectrum due to the approach or recession of the source of light is now so thoroughly well known, and has become of such importance in astronomical questions, that a laboratory experiment to illustrate this fact will be of interest. The idea, which we owe to the Russian astronomer, A. Belopolsky, and which was published in the *Memorie della Società Degli Spettroscopisti Italiani*, is as follows:—We know that the wave length of light ray can be varied by reflecting the light into a movable reflector, the amount of variation depending on the velocity of the reflector and the angles of incidence and reflection. By allowing the light to fall as vertical as possible on to the reflector, the variation of the wave-length can be magnified at will by increasing the number of reflectors. Now the apparatus suggested consists of two cylinders with parallel axes capable of being rotated very rapidly in opposite directions. On the surfaces of each a large number of reflectors are fixed, which are so arranged that when a ray of light from a heliostat falls on the reflector of the first cylinder, then from this on to a reflector on the second cylinder, and so on backwards and forwards, and finally into the slit of a spectroscope.

By closing first half the slit and photographing the spectrum, and then, on the same plate, photographing again the spectrum, only this time using the other half of the slit, the movement of the lines will thereby be doubly recorded on the plate, the double displacement being due to the two directions of rotation of the cylinders during the first and second exposure respectively.

Whether this idea can be carried out practically is yet to be seen, for there are many difficulties connected with it, such as the great velocities of the cylinders, perfect rigidity, &c., which will be hard to overcome.

THE PRÆSEPE CLUSTER.[1]

THIS work belongs to a class of investigations whose number has been steadily increasing in the last few years. The discussion of the relative motion of stars in loosely aggregated groups is a study that may throw light on intricate questions connected with the structure of the cosmos; and in this point of view, the Pleiades group has been discussed by several astronomers since Bessel laid the foundation for such inquiries more than fifty years since. The cluster in Perseus, the stars about the nebula of Orion and some other groups have already engaged the attention of astronomers, but nothing more complete or more interesting has appeared than the present investigation due to Dr. Schur; and it will hold its own till lapse of time gives a more trustworthy hold upon the small mutual displacements which successive investigations may reveal, for greater accuracy of measurement can scarcely be expected.

The present work divides itself naturally into three sections. In the first is given the results of a thorough examination of the instrument and of the constants of reduction, together with the triangulation of the group undertaken by Dr. Schur. In the second part is presented the measurements of position angle and distance of the stars by Dr. Winnecke, made with the Bonn heliometer in 1857 and 1858; and in the third, the comparison of the results of the measurements made with the Bonn and Göttingen heliometers respectively.

The investigation of the errors that accompany heliometrical measurement and their elimination, however complete and satisfactory, will only be of interest to experts in the use of this delicate instrument; but as evidence of the accuracy finally attained, we may quote the resulting values of the scale, derived from the measurement of the distances between stars in different parts of the heavens, whose places were determined with great accuracy for the reduction of the heliometer observations made in the Transit of Venus expedition. The places of the "Victoria" stars have been taken from Dr. Gill's paper:—

	Dr. Schur's value.	Dr. Ambronn's value.
	$''$	$''$
Stars in Cygnus	40·01601	40·01915
,, Hydra	40·01506	40·01610
,, near Pole	40·01562	40·01678
"Victoria" stars	40·01750	40·01710

In a measurement of approximately 2°, the two observers would assign values different by only 0″·22, a degree of accuracy upon which they may be congratulated.

[1] "Astronomische Mittheilungen von der Königlichen Sternwarte zu Göttingen." Die Oerter der helleren Sterne der Praesepe. Von Dr. Wilhelm Schur. (Göttingen, 1895.)

Notwithstanding this apparent accuracy, there still remains an unexplained discrepancy between measures made with the heliometer and the distances deduced from meridian observations. Dr. Gill has called attention to this peculiarity, and has suggested an explanation which does not seem to be satisfactory to Dr. Schur, or to apply to the Göttingen instrument, where a distance of about 1000″ appears to be measured too small by approximately a quarter of a second. This difference disappears for distances of about 5000″, and reappears with an opposite sign for the greatest distances possible to measure with the Göttingen heliometer. Dr. Schur employs, and justifies the employment of an empirical correction of the form—

$$\text{Correction} = a_s + bs^2 + cs^3$$

where the unit of s is 1000 seconds. On the assumption that the correction disappears for $s = 5$, and is at a maximum for $s = 1·3$, he derives the following values for the coefficients:—

$$\text{Correction} = 0''·473\,(s - 0·50s^2 + 0·06s^3).$$

The investigation of the corrections to the readings of the position circle is made with quite as much care as that devoted to measures of distance, but the probable error of a distance measure is only half as great as that of a measure of angle. This result, confirmed as it is by similar discussions in the case of other heliometers, induces Dr. Schur to base his triangulation of the group on measures of distances, reserving the measures of position angle for the orientation of the entire group after the solution of the triangles. The observations began in February 1889, and are continued till March 1892, and embrace forty-five stars of the group. The combined measures give rise to 123 measured distances, and each of these is compared with the distance computed from Asaph Hall's catalogue of the stars of the Præsepe Group ("Washington Observations," 1869, Ap. iv.), giving rise to as many equations of condition. These are collected into an enormous normal equation of seventy-four unknowns. The solution of such an equation is sufficient to make the boldest arithmetician waver, and seek some approximate solution, but Dr. Schur preferred to adhere strictly to the method of elimination proposed by Gauss, and after weeks of labour brought his work to a successful conclusion. Such a labour so carried out in the University of Gottingen, is a not unfitting tribute to the memory of the great mathematician whose name is connected with that particular form of solution. With a similar disregard to the quantity of labour involved, and with all the accuracy attainable, Dr. Schur finally fixes the coordinates of the forty-five stars under consideration.

A melancholy interest is attached to the second part of the memoir in which the results of Winnecke's measures are given to the world. The introduction is the work of that distinguished astronomer, and it will be a matter of sincere regret to all that his state of health has not permitted him to continue to the end an investigation of so much value and thoroughness. That the task of completion and editing has fallen to Dr. Schur is fitting and appropriate, and must have been to him a labour of love. The principal difference in the methods of observation at Bonn (where Winnecke's observations were made) and Göttingen consists in the greater reliance placed by Winnecke on the measures of position angle, a confidence scarcely warranted by the probable error deduced from the observations, which Dr. Schur gives as follows:—

Probable error in distance of 2000″ ... $= \pm\, 0''·218$
,, ,, in position angle (in a great circle) $= \pm\, 0''·379$

The final result is to give a catalogue of the places of 45 stars for the epoch 1858, which are comparable with the catalogue of Dr. Schur for the epoch 1890·54. The comparison of these two catalogues and the discussion of the proper motion forms the third section of the work.

Dr. Schur first examines the relative accuracy of the two catalogues, and decides in favour of the more modern, in the proportion shown by the following:—

	Göttingen.	Bonn.
Probable error of distance (4000″)	$\pm\, 0''·193$ ...	$\pm\, 0''·354$
,, ,, position angle	$\pm\, 0''·359$ ...	$\pm\, 0''·506$

From considerations based on these and similar facts drawn from meridian observations, Dr. Schur concludes that a difference of 0″·27 in the place assigned to a star in the two catalogues can hardly be regarded as a proof of the existence of proper motion. The difference between the coordinates both in R.A. and Declination, though larger than this quantity, is everywhere small and negative. The proper motion of ten of the stars has also been

determined by Dr. Auwers from the meridian observations of Bradley and Mayer, and these show in the mean a correction to the heliometrically deduced proper motions of $-0''.0003$ and $+0''.030$ in R.A. and Declination, respectively. This discrepancy is subsequently traced to corrections due to the fundamental catalogues employed, and the final star places given on p. 208 9 possess an accuracy that will make them of value for many purposes.

Finally, a comparison is instituted between the proper motion of the group as observed, and the motion that might be expected from the progressive motion of the solar system. The result is not in very satisfactory agreement. The parallactic displacement of the solar system is

	$\Delta\alpha$	$\Delta\delta$
	$0''.0010$	$-0''.020$
Proper motion, Auwers	$-0''.0044$	$+0''.007$
„ „ other sources	$-0''.0041$	$-0''.032$

The question of absolute parallax enters here, and to this point Dr. Schur promises to return, possibly in connection with photographic researches.

W. E. P.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE following appointments have recently been made abroad:—Bale, Dr. R. Metzner, of Freiburg, to the Chair of Physiology: Barcelona, Dr. Gil Saltor Lavall to the Chair of Surgical Pathology: Breslau, Dr. Jacobi, Professor of Forensic Medicine: Bonn, Dr. Finkler, Ordinary Professor of Hygiene: Columbian University, Wisconsin, Dr. W. Reed to the Chair of Bacteriology and Pathology, and Dr. M. T. Phillips to that of Hygiene: Granada, Dr Rafael Molla y Rodriguez, of Havana, Professor of Clinical Surgery: Genoa, Dr. Canalis, Ordinary Professor of Hygiene: Harvard, Dr. H. C. Ernst, Professor of Bacteriology: New York (Polyclinic) Dr. Wilbur B. Marple Professor of Ophthalmology, Dr. W. R. Pryor Professor of Gynæcology, and Dr. W. R Townsend, Professor of Orthopædic Surgery: Prague (Bohemian University), Dr. J. V. Rohon Extraordinary Professor of Histology: Tomsk, Dr. F. Kruger Extraordinary Professor of Medical Chemistry: Wurzburg, Dr. K. Rieger Ordinary Professor of Psychiatry: Zurich, Dr. H. von Wyss Extraordinary Professor of Forensic Medicine.

DR. J. H. HYSLOP has been appointed Professor of Logic and Ethics in Columbia College, New York. Dr. J. Allen Gilbert, of Yale, goes to the University of Iowa as Assistant Professor of Psychology.

ACCORDING to *Science*, Dr. Wilhelm Roux, of Innsbruck, has been called to the chair of Anatomy in the University of Halle; Dr. K. Seubert, of Tubingen, to the chair of Chemistry in the Technical High School, Hanover, and Dr. Kallius, of Göttingen, to the chair of Anatomy at Tubingen.

MESSRS. E. B. TITCHENER AND J. E. CREIGHTON have been made full professors in the Sage School of Philosophy in Cornell University.

PROF. MARK W. HARRINGTON has accepted the presidency of the University of Washington.

THE Aberdeen Town Council have agreed to give an annual contribution of £200 for the establishment of a department for instruction in agriculture, in connection with the University of Aberdeen, provided that a similar sum be given by the County Council.

THE prospectus of the Science, Art and Technical Schools, Plymouth, for the fourth session, 1895-96, has been issued. Copies may be had of the Secretary.

WE have received a copy of the syllabus of lectures to be delivered in the Engineering Department of the City of London College, Moorfields, during the coming session.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 9.—M. Marey in the chair.—A memoir was presented by M. Wladimir de Nicolaiew, entitled "On an attempt to show currents of electric displacement [illegible] the magnetic induction of iron in the alternative [illegible]."—Results of solar observations, made at the Royal Observatory of the Roman College, during the first quarter of 1895, by M. P. Tacchini. The diminution of frequency of spots was maintained during this quarter with a secondary minimum in January. Protuberances showed the same minimum although the season was unfavourable for their observation.—On the forces developed by differences of temperature between the two main plates of a beam with continuous trusses, by M. H. Deslandres. From the experiments made, differences of temperature between the upper and lower plates of a continuous girder cause supplementary forces of compression and extension, frequently reaching in the hot season 2 kg. per millimetre.—Observations on M. Deslandres' note, by M. Maurice Lévy. An exact demonstration giving the means of deducing the strains in every case.—On a theorem in geometry, by M. Mendeléef.—On nitro-substitutions, by MM. C. Matignon and Deligny. The conclusions are given: (1) Isomerides of position have always been found to have the same heats of combustion within the errors of experiment; one only need be examined from a number of isomerides. (2) The mean difference in heats of combustion of a compound and its nitro-derivative is 45 Cal. Hence is deduced the equation

$$RCH + NO_3H \text{ liq.} = RCNO_2 + H_2O \text{ liq.} + 36.7 \text{ Cal.}$$

that is, the exact value found by Berthelot for the formation of nitro-hydrocarbons.—On the explosion of endothermic gases, by M. L. Maquenne. The conditions of propagation of an explosive wave initiated by detonators are given, and the influence of this explosive character on the industrial applications of acetylene is pointed out.—Influence of the winter 1894-95 on the marine fauna, by M. Pierre Fauvel.—On a gigantic terrestrial tortoise, from a specimen living in Egmont Islands, by M. Th. Sauzier. Dimensions are given of a specimen of *Testudo Daudinii*, and compared with the dimensions of other known tortoises and the fossil *T. Perpiniana*. Results of palæontological excavations in the Upper Miocene of the "colline de Montredon," by M. Ch. Depéret.—On a superior limit to the mean area affected by an earthquake, by M. F. de Montessus de Ballore. From Japanese observations it is deduced that this higher limit is 1200 square kilometres.

PERSONALITY.

The Diseases of Personality. By Th. Ribot. Authorised translation. Second revised edition. (Chicago: The Open Court Publishing Company, 1895.)

THE importance of a work bears little relation to its bulk, so no surprise need be felt at a masterly and very suggestive *résumé* of recent inquiries into a question of the highest interest being compressed into this thin volume of less than 160 pages of good readable type. The work itself is not new, though it is so in its present translated form. It is practically up to date, and affords an excellent study for those to whom what Tennyson calls "the abysmal deeps of Personality" are wholly mysterious, as well as to those others who have sounded them in part.

First as regards consciousness: there are two views, the old and the new. The old view regards it as the fundamental property of the soul or mind; the new view regards it as an event superadded to the more regular activity of the brain, depending on conditions as yet unknown, and appearing or disappearing according to their presence or absence. The old view fails to account for the vast substratum of unconscious mental activity whose existence is now beyond dispute, and it apparently fails to account for intermissions of consciousness, whose existence can hardly be denied even when the fullest allowance is made for the effects of forgetfulness. The new view is simpler than the old one, and much more consistent with observed facts, especially such as are obtained from the study of mental disease, which is a subtle analyser of mental functions. Many persons are loth to admit that the highest manifestations of the human mind are fugitive phenomena, subordinate to those of a lower grade; but whatever be the origin of consciousness, its value is none the less. From the point of view of the evolutionist, it is not the origin of a faculty that is of consequence, but the elevation to which that faculty attains. However consciousness may have come into existence, its first appearance on the earth must have been a fact of the first magnitude, for it is the basis of the recollections, which capitalise the past of each animal for the profit of its future, and give it new chances of survival. On the automaton view of life, consciousness changes the animal from a simple automaton into one of an incomparably higher order. The author quotes much from "Les colonies animales" of Perrier, to show the steps through which consciousness first became developed in the animal world, starting from associations of individuals that are almost independent of one another, but which, owing to their contiguity and mutual pressure, cannot be wholly unaffected by their neighbours. The next step is the appearance of a colonial consciousness, where a colony is formed of individuals in which some division of labour takes place, and the function of locomotion is centralised. But because a colony acquires colonial consciousness, it does not follow that each of the individuals that compose it loses its particular consciousness; thus the severed ray of a star-fish continues to creep, to follow, or, it may be, to deviate under conditions from a given route, and to quiver when excited, and thus to betray a consciousness of its own which, before it was severed, was subordinated to the consciousness of the whole star-fish. By degrees this colonial consciousness confiscates for its benefit all the particular ones.

The author maintains that consciousness is not like a central point from which alone feelings radiate and to which they all arrive, but that it is a complexus of separate phenomena, each of a particular class, bound up with certain unknown conditions of the brain, existing only when they exist, lacking when they disappear. Hence the sum of the states of consciousness in man is very inferior to the sum of all his nervous actions. Conscious personality is only an abstract of the vast amount of work that takes place in the nervous centres. Its basis is formed by the diffused bodily sensations which, being elementary causes, serve as a warp upon which is woven some gorgeous pattern of tapestry that corresponds to the higher feelings. The general consciousness of the organism serves as the support of all the rest, and forms, in the author's opinion, the real basis of conscious personality.

Personal identity is an unsatisfactory phrase. A man feels to be the same in his ego at different periods, because the great majority of his bodily feelings continue the same, owing to his structural sameness. The so-called identity is due to the large preponderance of unchanging elements, which characterise a healthy state; but in disease this habitual predominance may fail either wholly or temporarily, leading in the one case to a sense of a complete change of personality, in the other to that of multiple and alternating personalities. A few but adequate number of specimen cases are given. A somewhat comic instance is that by Hack Tuke, of a patient who had lost his ego (that is the one which was familiar to him), and was in the habit of searching for himself under his bed. (*Cf.* the speech of Saturn, "Search Thea, search . . ." in Keats' "Hyperion.")

The rather common cases in which a man believes himself to have become changed into a new person, are considered by the author to be mostly superficial; that is, to be due to local rather than to general disorder. I myself witnessed a case which showed that the imagined personality was not well sustained. It was at a lunatic asylum, where I went accompanied by a photographer to take specimens for composite photography. He mounted his camera in a ward, and a batch of patients were brought up. One of them was duly placed in front of the camera, the others were led to a bench behind the operator to wait their turn. It happened that one of these had the mania that he was a great commander, let us say, Alexander the Great, and he chafed internally at not having had precedence. When my photographer's head was under the dark cloth, and his body in the attitude appropriate to the occasion, Alexander the Great could restrain himself no longer, but nipped the projecting rotundity of the poor man's hinder end with his teeth. I abstain from dwelling on the tableau, or on the care with which the smarting photographer, in his further operations, squeezed himself into a corner that guarded his rear. The point is this, that a man who was thoroughly pervaded with the idea of being

a mighty conqueror, would not have made that kind of attack.

Without attempting to condense further this already condensed and very readable little volume written by a distinguished inquirer, I will conclude by saying that it well deserves a place in any general library.

FRANCIS GALTON.

SATELLITE EVOLUTION.

Satellite Evolution. By James Nolan. Pp. 114. (Melbourne, &c.: George Robertson and Co., 1895.)

IN this book Mr. Nolan discusses the part played by tidal friction in the evolution of satellites. Although the subject is one of much scientific interest, his work is hardly likely to attract the attention it deserves, because the unmathematical reader will find the reasoning hard to follow, whilst the mathematician will be repelled by prolixity, due to the author's treatment of the problem by means of general reasoning.[1] The first fifty pages of the book appear to be virtually contained in the single equation which states the effect of tidal friction in increasing the mean distance of a satellite. It might perhaps be interesting to some to discuss the various elements of the problem in detail, but those who are able to comprehend an analytical formula are not very likely to have the patience to follow such a discussion.

I shall not accordingly follow Mr. Nolan in detail, but will pass at once to the conclusion to which he tends. On p. 9 he says:—

"Though Mr. Darwin made elaborate calculations to support his theory respecting the part played by tidal friction on the evolution of the earth and moon, he seems to have dismissed the Jovian and Saturnian systems with the conclusion that their satellites, unlike our moon, could not be traced much further in than the present distances of their respective planets; and that as the relation between the mass of the planet and satellite, or relation of rotational to orbital momentum is very different in the case of the earth and moon to that for other planets and satellites, their modes of evolution may have differed considerably. He seems to have gone something further into the possible effects of solar tidal friction on the planets revolving round the great central body, or at least has come to the correct conclusion that the efficiency of such tides would be too small to effect any appreciable change during the natural lifetime of a solar system."

He then proceeds to show that, if the earth and Jupiter rotate under the influence of tides subject to the same frictional resistance, the proportionate rate of increase of the moon's mean distance is much smaller than that of all of Jupiter's satellites, save one. In other words, four out of five of Jupiter's satellites would have their mean distances increased by, say, one per cent. in a much shorter time than would the moon. He then pursues the same train of reasoning with respect to Saturn and Mars.

It appears to me that Mr. Nolan is correct in these conclusions, and we are thus led to suppose that tidal friction may have played a much more important part in the evolution of satellites than I was disposed to allow it.[1] He points out (p. 70) that the satellites of Jupiter are probably much younger than the moon; "when the moon was younger, her relative rate of recession was faster, as now is the case for some satellites in other systems." He finally concludes (p. 78) that the majority of satellites in each system may be traced to a position corresponding with that of the rings of Saturn.

But before arriving at this result, the author has treated another problem, in which, in my opinion, his conclusion is incorrect. On p. 45, he considers the effects of tidal friction on such a ring as that of Saturn. He says:—

Tidal friction "could have no effect if the ring were perfectly even all round. When composed of individual bodies it could not be or remain so. Each individual would be unaffected by the tides of the others, and would recede at the same rate as if it were the only body in the ring. The moon recedes at exactly the same rate as she would were there no solar tides: and if there were a second moon there would be no interference with the recession of the first . . . Then if the bodies composing the rings are 'as the sand on the sea shore for multitude' tidal friction must still effect the usual progressive change, unless each individual body be small enough to be unaffected at the distance, whether composing a ring or not. This must have a dissolving effect on the ring, or tend to shape certain sections of it into so many bodies, which, having increased their mass at the expense of the ring, finally recede therefrom, either to circle round at a great distance or be precipitated into the planet increasing its rotation speed."

It would seem that the process here sketched is an essential part of Mr. Nolan's theory of the evolution of satellites, but I believe it to be founded on erroneous premises. He omits in fact to notice the necessary condition for neglecting the effects of the tides raised by one satellite on the mean distance of another; this is, that the periodic times of the two shall not be equal to one another. If the periodic times of two satellites are unequal, we need not invoke tidal friction to bring the two bodies near to one another. On the other hand, if four or eight satellites be equally spaced round a planet and revolve with the same periodic time, tidal friction would only influence their motions to a very small extent. I am therefore unable to follow Mr. Nolan in this part of his work.

Several other points in the early history of satellites are considered by Mr. Nolan, but I am unable to touch on them within the limits of a review.

Notwithstanding all that has been written by him and others, we are still far from a consistent theory of the formation of a satellite. In my own papers I have ventured to throw out suggestions (which have but too often been quoted as positive theories), and it still seems to me at least, that neither the present contribution of the author nor the theories of others are adequate.

This work touches on subjects of interest, and although it seems open to much criticism, I for my part welcome the extension given by Mr. Nolan to the part played by tidal friction in evolutionary astronomy.

G. H. DARWIN.

[1] [illegible]

[1] The argument by which I was led to an erroneous conclusion on this point will be found in *Phil. Trans.*, part ii., 1881, p. [illegible].

OUR BOOK SHELF.

Die Lehre von der Elektrizitat und deren Praktische Verwendung. By Th. Schwartze. (Leipzig: J. J. Weber, 1895.)

THE author in his preface says that his intention in writing this book was to give the bearing of the latest scientific results in electricity on electro-technology. He goes on to say that the contents will probably appear peculiar. The first of the above statements, taken in conjunction with the title of the book, will probably give as erroneous an idea of the contents as it is possible to obtain. For if there is one thing the author does not do, it is to give the bearing of the few modern discoveries, or lines of thought, which he mentions on the practical applications of electricity.

For all intents and purposes the book may be divided into two parts. The first of these deals with the question of the fundamental principles of general physics and with some mechanical problems, such as moment of inertia, oscillations of a pendulum, wave-motion, &c. The second part deals more particularly with electric and magnetic phenomena.

Throughout the greater part of the book, but particularly in the first part, the reader will probably heartily endorse the author's view, that the contents of the book are peculiar; for the subject of dimensions is treated at great length, so that, for at any rate the first three hundred pages, there is hardly a page without at least one dimensional equation. The appearance of some of these dimensional equations, however, are certainly peculiar, for the author attempts to introduce a set of dimensions in terms of what he calls "Linearkraft," "Flächenkraft," and "Volumenkraft." These quantities he indicates by the symbols L, L^2 and L^3, regardless of the fact that in those dimensional formulæ, in which length, mass, and time are taken as the fundamental units, the symbol L is used for a length. Even the author himself seems to have got muddled when such equations as $[M^2L^2]=[ML^2]$ are allowed to appear, and the state of mind of the student, whose command of dimensions is limited, after reading the book, is lamentable to think of. In the chapter dealing with the dimensions of the electrical and magnetic units, no mention is made of the effect of the properties of the medium, and although Rücker's name is mentioned in the preface in connection with the subject of dimensions, no mention is made of his proposal to consider the specific inductive capacity and the permeability of the medium as subsidiary fundamental units, and to indicate their presence in the dimensional formulæ. The more purely electrical portion of the book calls for little remark, and contains a somewhat elementary treatment of the subject of electrostatics, such as the calculation of the capacity of some simple forms of condensers, &c. There are also chapters dealing with uni-directed currents, thermo-electricity, electrolysis, electro-magnetic induction, and the dynamo. Finally, about seventy pages are devoted to what is called "electro-tectiniches," in which the commoner forms of electrical measuring instruments are shortly described.

While only a very short account is given of Hertz's work, contrary to what one would expect in a German work, considerable space is devoted to a description of Elihu Thomson's more showy experiments with rapidly alternating currents.

LETTERS TO THE EDITOR.

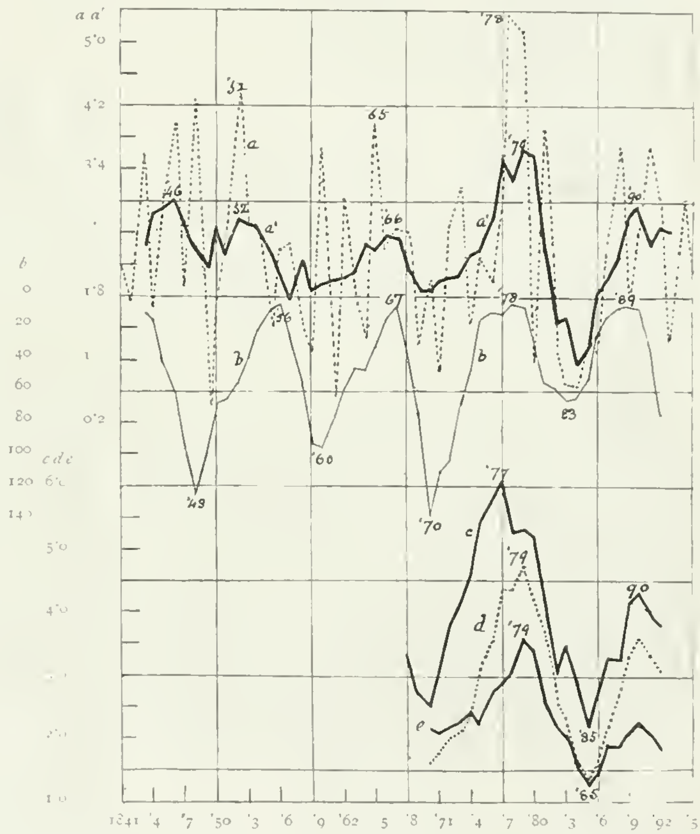
[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Rain in August.

AUGUST being a harvest month, and the holiday month *par excellence* in this country, its weather is a matter of concern to multitudes. I propose to show how the rainfall of August at Greenwich has varied in the last half-century (1841–95).

This variation appears to me rather to suggest sun-spot influence: but whatever may be thought about this, it may be interesting to observe how far the kind of correspondence here pointed out is maintained in the future.

In the accompanying diagram we have (*a*) a dotted curve showing the variation of August rainfall, and the values have been smoothed with averages of 5, yielding the continuous curve *a'*. Underneath (*b*) is an inverted sun-spot curve.



a. Rainfall in August, Greenwich. *a'*. The same, smoothed (5-av.). *b.* Inverted sun-spot curve. *c, d, e.* Rainfall in August at Haverfordwest, Llandudno, and Boston (smoothed).

A considerable correspondence may here be traced, especially in the last three waves; the crests or maxima of the smoothed rainfall curve coming near the sun-spot minima, and the hollows or minima of the former near the sun-spot maxima.

It seems specially noteworthy that in each year following a sun-spot maximum year we have had a very dry August. Thus (the August average being 2·38) we have:

Sun-spot max.	1848	...	Rainfall of August		1849, 0·45 in.
,,	1860	...	,,	,,	1861, 0·57 ,,
,,	1870	...	,,	,,	1871, 0·86 ,,
,,	1883	...	,,	,,	1884, 0·67 ,,

The data previous to 1841 are, I suppose, less reliable: but I may add these two cases of August rainfall under average:

Sun-spot max. 1830	...	Rainfall of August 1831, 2·14 in.
" 1837	...	" " 1838, 0·93 "

By way of showing that in other parts of the country there has been, in recent years at least, a similar variation, I add three similarly smoothed curves of August rainfall for Haverfordwest, Llandudno, and Boston (Lincoln) respectively ([illegible], *d*, *e*). The data, however, do not extend back further than 1866.

The case of Greenwich may be presented as follows:—Take each maximum sun-spot year, and a year on either side, and tabulate the August rainfall in each of these. Indicate by the letters *d* (for dry) and *w* (for wet) whether this rainfall has been below or above the average. Then we have:

Maximum.						
1847, 1848, 1849	...	1·95	4·25	0·45	...	*d w d*
1859, 1860, 1861	...	1·13	3·68	0·57	...	*d w d*
1869, 1870, 1871	...	1·21	2·02	0·86	...	*d d d*
1882, 1883, 1884	...	1·16	0·71	0·67	...	*d d d*

Here we find ten cases of a dry August out of twelve. Those twelve values give an average of 1·55 inches.

Now do the same with minimum sun-spot years:—

Minimum.						
1842, 1843, 1844	...	1·78	3·62	1·71	...	*d w d*
1855, 1856, 1857	...	1·40	2·42	2·50	...	*d w w*
1866, 1867, 1868		2·42	2·04	2·61	...	*w w w*
1877, 1878, 1879	...	2·00	5·38	5·19	...	*w w w*
1888, 1889, 1890	...	3·73	1·81	2·54	...	*w d w*

Here we find eleven cases of a wet August out of fifteen. Those fifteen cases give an average of 2·84 inches.

It would be interesting to know to what extent such relations exist elsewhere, and perhaps some of your readers may be disposed to investigate the matter.

A. B. M.

Alteration in the Colours of Flowers by Cyanide Fumes.

It is well known that the yellows of some insects are turned to red by the fumes from potassium cyanide; but I have not, after some inquiry, been able to obtain any literature describing the effects of said fumes upon the colours of flowers. The reactions I have observed are very curious, and while it seems improbable that they are hitherto wholly unknown, it may not be amiss to direct attention to them. A few lumps of the cyanide are placed in a corked tube, covered with a little cotton, and the flowers are placed on the cotton. It is probably necessary that the day should be hot, or the tube slightly warmed. The pink flowers of *Cleome integrifolia* and *[illegible]* turn to a brilliant green-blue, and finally become pale yellow. A purple-red *Verbena* becomes bright blue, then pale yellow. The purple flowers of *Solanum elaeagnifolium* go green-blue and then yellow. The white petals of *Argemone [illegible]* turn yellow—the natural colour of *A. mexicana*. The pale yellowish flowers of *Mentzelia nuda* turn a deeper yellow. Flowers of *[illegible]*, var., turn pale yellow. White flowers of *[illegible]* turn yellow. The scarlet flowers of *[illegible]* turn pale dull pink, resembling somewhat a natural variety of the same. Any of your readers will doubtless obtain similar results with the flowers growing in their vicinity.

T. D. A. COCKERELL.

Las Cruces, New Mexico, U.S.A., September 3.

ON THE CONSTITUENTS OF THE GAS IN CLEVEITE.

WE have investigated the spectrum of the gas discovered in the mineral cleveite by Ramsay, and have found it to be most regular. It consists of six series of lines, the intensity of the lines in each series decreasing with decreasing wave-lengths. Similar series of lines have been observed in many spectra. The first series was discovered by Dr Huggins in the ultra-violet spectra of a number of stars. It proved to belong to hydrogen, and to be the continuation of the four strong hydrogen lines in the visible part of the spectrum. Johnstone Stoney had already shown that three of the wave-lengths of the visible hydrogen lines were most accurately proportional to the values 9/5, 4/3, 9/8, when Balmer discovered that these values were given by the formula

$$\frac{m^2}{m^2 - 4}$$

for $m = 3, 4, 6$, and that the other wave-lengths of the series were proportional to the values obtained by substituting for m the other entire numbers greater than three. The series has now been followed from $m = 3$ to $m = 20$, the lines growing weaker and weaker to the more refrangible side, and approaching each other closer and closer. The formula shows that they approach a definite limit for large values of m. This is seen more clearly when we consider wave-numbers instead of wave-lengths, which according to the formula would be proportional to

$$1 - \frac{4}{m^2}.$$

Many series of lines similar to the hydrogen series were discovered by Liveing and Dewar. They have called them harmonic series, and have compared them to the series of over-tones of a vibrating body. They have been further studied by Rydberg and by Kayser and Runge. We cannot here enter into any detailed account. We only want to explain so much as to make the conclusions understood which we have drawn from the spectrum of the gas in cleveite. The wave-lengths λ of the lines belonging to the same series are always approximately connected by a formula somewhat similar to Balmer's

$$1/\lambda = A - Bm^{-2} - Cm^{-4}.$$

A determines the end of the series towards which the lines approach for high values of m, but does not influence the difference of wave-numbers of any two lines. B has nearly the same value for all the series observed, and C may be said to determine the spread of the series, corresponding intervals between the wave-numbers being larger for larger values of C. As B is approximately known, two wave-lengths of a series suffice to determine the constants A and C, and thus to calculate approximately the wave lengths of the other lines. It was by this means that we succeeded in disentangling the spectrum of the gas in cleveite, and showing its regularity.

In the spectrum of many elements two series have been observed for which A has the same value, so that they both approach to the same limit. In all these cases the series for which C has the smaller value, that is to say which has the smaller spread, is the stronger of the two. In the spectrum of the gas in cleveite we have two instances of the same occurrence. One of the two pairs of series, the one to which the strong yellow double line belongs, consists throughout of double lines whose wave-numbers seem to have the same difference, while the lines of the other pair of series appear to be all single. Lithium is an instance of a pair of series of single lines approaching to the same limit. But there are also many instances of two series of double lines of equal difference of wave-numbers ending at the same place as sodium, potassium, aluminium, &c. There are also cases where the members of each series consist of triplets of the same difference of wave-numbers as in the spectrum of magnesium, calcium, strontium, zinc, cadmium, mercury. But there is no instance of an element whose spectrum contains two pairs of series ending at the same place. This suggested to us the idea that the two pairs of series belonged to different elements. One of the two pairs being by far the stronger, we assume that the stronger one of the two remaining series belongs to the same element as the stronger pair. We thus get two spectra consisting of three series each,

two series ending at the same place, and the third leaping over the first two in large bounds and ending in the more refrangible part of the spectrum. This third series we suppose to be analogous to the so-called principal series in the spectra of the alkalis, which show the same features. It is not impossible, one may even say not unlikely, that there are principal series in the spectra of the other elements. But so far they have not been shown to exist.

Each of our two spectra now shows a close analogy to the spectra of the alkalis.

We therefore believe the gas in cleveite to consist of two, and not more than two, constituents. We propose to call only one of the constituents helium, the one to which the bright yellow double line belongs, whose spectrum altogether is the stronger one, while the other constituent ought to receive a new name.

We have confirmed this rather hypothetical conclusion by the following experiment. The connection leading from our supply of cleveite gas to the vacuum tube contained a side branch parting from it and joining it again. There were stopcocks on either side of the side branch, and a third one in the side branch. In the main tube between the ends of the side branch a plug of asbestos was tightly inserted. To prepare the vacuum tube only the tap leading to the supply was closed, the whole space up to this tap being carefully evacuated. Now the side branch was closed, and the tap leading to the supply was opened. Then we observed that the light of the electric discharge in the vacuum tube was at first greenish, and after a while grew yellow. By cutting off the current of gas after a sufficiently short time, we succeeded in making a vacuum tube which remained greenish. On examining it in a small spectroscope with which we could overlook the whole spectrum, we found that the intensities of the lines had changed. The yellow line was scarcely as bright as the green line 5016, and the red line 7065 had apparently decreased relatively to 7282 and 6678, although it was still stronger than 7282. The two lines that had decreased in intensity belong to the second set of series, while the others are members of the first set. The other visual lines of the second set could not very well be examined because they are more in the violet part.

This observation confirms our spectroscopic result. The gas in cleveite may be taken to be a mixture of two gases of different density, of which the lighter one is more rapidly transmitted through the plug of asbestos. There is, however, the objection to be raised, that in the green tube the pressure is less, and that the difference of intensities is due to the pressure being different. This must be further inquired into.

We were not satisfied with the visual observation of the change of intensities in our green tube, but thought it desirable to test the conclusion by the bolometric measurement of the two lines that we have discovered in the ultra-red part of the spectrum. If we were right, the ultra-red line of smaller wave-length, which belongs to the second set of series, ought to have decreased in intensity relatively to the other ultra-red line. This we found to be so indeed. In the yellow tubes the intensity of the smaller wave-length was to that of the other on an average as 3 to 1, while in the green tubes it was as 1·8 to 1. This confirmation we consider the more valuable as it does not depend on any estimation which may be biassed by the personal opinion of the observer, but is based on an objective numerical determination.

Another confirmation may be gathered from the spectrum of the sun's limb and that of several stars. Let us confine our attention to the six strongest lines in the visible part of the spectrum :

7066, 6678, 5876, 5016, 4922, 4472.

The first, third, and sixth belong to the second set of series ; the second, fourth and fifth to the first set. These six lines have all been observed in the spectrum of the sun's limb, as Norman Lockyer and Deslandres have pointed out. Now, according to their appearance in the spectrum of the sun's limb, they may be classed in two groups, one group being always present, the other group being sometimes present. C. A. Young long ago called attention to the difference in the frequency of appearance of the chromospheric lines. He has given them frequency numbers, roughly estimating the percentage of frequency with which the lines were seen during the six weeks of observation at Sherman in the summer of 1872. According to Young, 7066, 5876, 4472 have the frequency number 100, while 6678, 5016, 4922 have the numbers 25, 30, 30, showing that one of the two constituents was always present, while the other was only seen about once in every four cases.

The lines of both constituents have been observed in the spectra of a considerable number of stars β, δ, ϵ, ζ, γ Orionis, α Virginis, β Persei, β Tauri, η Ursæ majoris, β Lyræ. In the spectrum of β Lyræ, thirteen lines have been identified with certainty. But the most interesting case in point is the spectrum of Nova Aurigæ, that wonderful star whose sudden appearance was announced to astronomers in 1892 by an anonymous post-card. In the spectrum of Nova Aurigæ the two lines 5016 and 4922 were very strong, while 4472 was weak and 5876 has only been seen by Dr. Huggins, we believe only on one occasion, and appears to have been very weak. Now 5016 and 4922 belong to the lighter constituent, and are together with 6678 the strongest lines in the visible part of the spectrum ; while 5876 and 4472 are the strongest lines of the other constituent in the visible part of the spectrum. In Nova Aurigæ, therefore, the lighter constituent gave a much brighter spectrum than helium proper. But there may here be raised an objection, which indeed we do not know how to refute. Why has the line 6678 not been observed ? It is a pity that the red part of the spectrum cannot be more easily photographed. Nova Aurigæ has now become very weak, and besides the spectrum is quite altered, so that we shall never know whether the red line 6678 was really absent or has only escaped notice.

From the fact that the second set of series is on the whole situated more to the refrangible part of the spectrum, one may, independently of the diffusion experiment, conclude that the element corresponding to the second set is the heavier of the two. In the spectra of chemically related elements like Li, Na, K, Rb, Cs, or Mg, Ca, Sr, or Zn, Cd, Hg, the series shift to the less refrangible side with increasing atomic weight. But it appears that in the spectra of elements following each other in the order of their atomic weights in a row of the periodic system like

Na, Mg, Al ;
K, Ca ;
Cu, Zn ;
Rb, Sr ;
Ag, Cd, In ;

the series shift the opposite way, so that the spectrum of the element of greater atomic weight is as a whole situated further to the more refrangible side. Now in our case the density of the gas has been determined by Langlet (published by Cleve) and by Ramsay to be about double the density of hydrogen. Assuming the atomic weights of the two constituents to be between that of lithium and that of hydrogen, they would both belong to the same row of the periodic system, and therefore the more refrangible set of series would correspond to the greater atomic weight.

For convenience of reference all the observed lines are given in the following table, the wave-lengths being abridged to tenth-metres.

Lighter Constituent.

C. RUNGE AND F. PASCHEN.

NOTES.

THE third International Congress of Zoologists (an account of the proceedings at which will appear in a subsequent issue of NATURE) has just been held at Leyden, and appears to have been a great success. No fewer than twenty nationalities were represented, and the arrangements for the comfort of the members were all that could be wished. It was decided to hold the next meeting (in 1898) in England, and Sir William H. Flower was elected President. During the meeting it was announced that the Senate of the University of Utrecht had conferred degrees upon Sir William H. Flower, M. Milne-Edwards, of Paris, and Prof. Weismann, of Freiburg.

TELEGRAMS from St. John's, dated September 22, announced the return, in the steamer *Kite*, of the Peary Expedition. The result of the expedition was a most disappointing one, as Lieut. Peary and his companions were unable to extend their journeyings beyond Independence Bay, which point was the furthest north reached by Lieut. Peary in his expedition of 1892. The main cause of failure was the loss of all the stores of provisions, save one, which had been got together and deposited along the intended line of march last year, all having been buried by perhaps the heaviest snowfall known, which obliterated all traces of them. The sufferings endured by the explorers, on the verge of starvation as they were for the greater part of the time, can hardly be estimated, and when, on July 31, the *Kite* arrived, they were utterly broken down and ill, but they subsequently recovered under careful treatment. The expedition, according to a later telegram, will not be entirely barren of scientific results, as Lieut. Peary is reported to have mapped Whale Sound, and completed his studies of the Eskimo Highlanders. He has also brought back another year's meteorological record. The relief expedition, too, is credited with obtaining the largest collection of Arctic fauna and flora ever acquired, and Prof. Salisbury, of Chicago University, did good geological work.

A COMMUNICATION was made to the press on Friday last by Reuter's Agency with reference to the movements of the Jackson-Harmsworth Polar Expedition. It was admitted that the intelligence received had been made in a somewhat meagre and disjointed form; but from it could be gleaned that on September 7 of last year the expedition arrived safely on the coast of Franz Josef Land and in the locality of Cape Flora. On September 10 the ice closed round the *Windward*, and she was frozen in for the winter. On February 23 the sun returned, and on March 10 Mr. Jackson started on his northern journey, with a quantity of stores, and made his first depôt. Various journeys to and fro with provisions, &c., were made, and depôts formed, the most northern of which was about 100 miles from the camp. The *Windward* has, it is expected, now set sail for home, bearing letters and journals of the early part of the expedition.

THE expedition to Alaska of the United States Geological Survey, for the purpose of examining into the coal and gold mines of the territory, has returned safely to San Francisco after a successful and very interesting season, during which, incidentally, many of the glaciers and volcanos were studied. Messrs. Becker and Dall will return to Washington by October 1, to submit their report upon the mineral resources to the Director of the Survey, which will be printed as soon as the necessary analyses, &c., can be made.

WE have to record the death, at Berlin, at the age of seventy-six, of Prof. Bardeleben, the eminent surgeon and author of "Lehrbuch der Chirurgie und Operationslehre."

THE death is announced, from Bendigo, Victoria, of Dr. Paul Howard MacGillivray, well known as a medical man and for his researches on Polyzoa.

AT the meeting of the Entomological Society of London, to be held on Wednesday, October 2, the following papers will be read:—"Contributions towards the History of Maruina, a New Genus of Diptera" (*Psychodidæ*), by Dr. Fritz Muller; "Remarks on the Homologies and Differences between the First Stages of Pericoma and those of Maruina," by Baron Osten Sacken.

THE annual meeting of the Federated Institution of Mining Engineers has just taken place at Hanley, and papers were read on "The Use of Steel Girders in Mines," "Economic Minerals of the Province of Ontario," and "Gold Mining in Nova Scotia." The Institution seems to be in a flourishing condition, the membership having risen from 1189 in 1889-90, to 2199 at the present time. The prizes for papers on "The Prevention of Accidents in Mines" have been awarded as follows: (1) Mr. A. Kirkup (2) Mr. W. N. Drew; Messrs. E. A. Allport and A. Noble were bracketed for the third place.

THE Royal Society of New South Wales offers its medal and the sum of £25 for the best communications (provided such be deemed of sufficient merit) on original research in the following subjects:—"The Origin of Multiple Hydatids in Man"; "The Occurrence of Precious Stones in New South Wales, with a description of the Deposits in which they are found"; "The Effect of the Australian Climate on the Physical Development of the Australian-born Population"; "The Physiological Action of the Poison of any Australian Snake, Spider, or Tick"; "The Chemistry of the Australian Gums and Resins"; "The Embryology and Development of the Echidna or Platypus"; "The Chemical Composition of the Products from the so-called Kerosene Shale of New South Wales"; "The Mode of Occurrence, Chemical Composition and Origin of Artesian Water in New South Wales." The competition is open to all, and is not subject to any restriction, save that the communication to be successful must be either wholly or in part the result of the competitor's own original observation or research. The suc-

cessful essays will be published in the Society's annual volume, and fifty copies of the paper will be supplied to their writers free of charge. Particulars as to the latest dates for sending papers, and all other necessary information, may be obtained from the Honorary Secretaries, at the house of the Royal Society of New South Wales, 5, Elizabeth-street, Sydney.

The Manchester Trades Council has recently passed a resolution strongly in favour of the Report of the Select Committee of the House of Commons on Weights and Measures, in which the Council expresses the hope that no efforts will be spared to make the Committee's recommendations law. As can be readily understood, the New Decimal Association is much encouraged by the attitude taken in so important a commercial centre as Manchester, and it is to be hoped that at no distant date their efforts will be crowned with success, and that the present cumbrous system will be for ever abandoned.

The metric system of weights and measures is to be obligatory in the United States of Mexico from September 16, 1896. This system has been in use in the Government departments of Mexico for some time past, but a decree recently passed makes it the sole legal system throughout the Republic, and will make an end of the various old Spanish measures hitherto in vogue in ordinary business transactions.

Dr. van Rijckevorsel and Herr van Bemmelen are engaged on a research which has for its object to determine the influence of elevation above sea-level on the magnetic elements. For this purpose an accurate magnetic survey must be made of some moderately high mountain, of non-magnetic material and sufficiently far removed from magnetic masses. The Righi seems to fulfil these conditions most satisfactorily; but in order to decide the matter, Herrn. van Rijckevorsel and van Bemmelen selected thirty stations, distributed on the low ground round the Righi in three concentric circles with the mountain as centre. The magnetic elements have been determined at these stations, but the calculations are not yet completed. If these indicate no traces of disturbance, due to the Righi or its surroundings, the survey of the mountain will be proceeded with.

The latest number of the *Records* of the Geological Survey of India contains a translation of a paper by Dr. F. Kurtz, on the Lower Gondwana beds of Argentina (from *Revista del Mus. de la Plata*). In this is recorded an important discovery of plant-remains in shales at Bajo de Velis. These fossils are well-preserved, and while being quite different from the Argentine plant-remains already found, show a close affinity to the plants of the Kaharbari beds of the Lower Gondwanas of India, as well as to those of the Ekka-Kimberley beds of South Africa, the Newcastle and Baccus-Marsh beds of Australia, and the Mersey beds of Tasmania. The previously-known plant-bearing beds of Argentina consisted of two series—one containing a Rhætic flora, resembling that of the Stormberg (Upper Karoo) beds of South Africa, the Hawkesbury beds of Australia, and the Rajmahal (Upper Gondwana) series of India; the other containing a flora of Lower Carboniferous character. The newly-discovered flora must be intermediate in age between these two—that is to say, it cannot be older than Upper Carboniferous, nor younger than Triassic; and with it must go the flora of the important coal-bearing Upper Gondwana beds of India. These have already been assigned to the Upper Carboniferous (at lowest) by Messrs. Medlicott and Blanford, and the Indian Survey, and the new discoveries in Argentina give a satisfactory confirmation of their views.

We note the publication of the first *Bulletin des Observations Météorologiques*, 1894, by the Observatory of St. Louis, St. Heliers, Jersey, containing monthly means from direct observations and from self-recording instruments. The Director of this new Observatory is the Rev. M. Dechevrens, who has already done good work at Zi-ka-wei, near Shanghai, and by the investigation of the typhoons of the China Seas, in connection with the Shanghai Meteorological Society. The St. Louis Observatory is provided with a tower about 150 feet high, for the special study of vertical wind currents and atmospheric electricity.

The Acclimatisation Society of Moscow must be credited with more than ordinary originality and ingenuity in its efforts to improve the system of bee-keeping in vogue among the Russian peasants. Antiquated and unremunerative methods of hive management are still in general use in Russia; and, in order to diffuse a knowledge of the more rational methods of modern apiarists, the Society last year organised a travelling bee-keeping exhibition upon a novel and, as it proved, most successful plan. A barge, 70 metres long and 8 metres broad, was procured and fitted up with a museum, a garden with trees and flower-beds, hives of all kinds, old and new, and a number of hives with living bees; there were also dwelling-rooms for the travelling staff. The museum contained examples of bee-keeping appliances and products, together with a set of preparations illustrating the structure and life-history of bees and their natural enemies. The staff in charge of the exhibition consisted of a practical bee-keeper, two entomologists, and ten men-servants for the vessel. The floating exhibition was towed down the river out of Moscow by twenty horses, ten on each bank; and six towns and about twenty villages were visited between the old capital and the town Kaluga. The travelling was done during the night. During the day, from 8 a.m. to 9 p.m., a halt was made at some town or village; the objects in the museum were explained to visitors by the staff, and the methods of working the model hives were demonstrated to the bee-keeping country folk. The exhibition has worked with great success. The great expense which this interesting and instructive exhibition demanded was most willingly defrayed by Herr F. Motschalkin, who is himself an enthusiastic bee-keeper.

A new determination of the lowest temperature at which a hot body becomes visible is published by Sgr. P. Pettinelli, in the *Nuovo Cimento*. He heated a cast-iron cylinder 30 cm. long and 14 cm. broad in a wrought-iron jacket over a Bunsen burner to a temperature of 460° C., as indicated by an air thermometer, and then observed its flat end in a dark room from a point 60 cm. above it. When it had cooled to about 415°, the red heat vanished and gave way to an indefinite hazy glow. This glow completely disappeared at 404°, and repeated observations gave an error of only 3°. Highly emissive substances, such as the "mantles" made by Auer and others for incandescent gas lighting, became visible at the same temperature; but reflecting surfaces had to be heated 20° higher before they appeared to the eye, and glass still more. These low temperature rays were found to traverse glass and water like ordinary light rays, but they suffer a comparatively greater absorption. Different eyes differ slightly in their capacity of seeing them, the maximum divergence being about 6°. But then the extent of surface must be the same. Sgr. Pettinelli found that if he screened off all but 1/40th of the surface, the body had to be heated 6° higher than before to become visible; if 1/200th, 20° higher: and if 1/800th only was exposed to view, the minimum temperature of visibility was 460°. Hence he rightly concludes that the contradictory results obtained by previous experimenters are due to differences in the areas of the hot bodies investigated.

The Irish elk (*Megaceros hibernicus*) has hitherto had a somewhat isolated position as the only species of its genus known to naturalists up to the present. A new claimant to the same generic title has, however, been recently unearthed in Germany,

and has been described by Prof. Nehring, of Berlin, under the name *M. Ruffii*. The new species is intermediate in many of its characters between the Irish elk and the fallow deer (*Dama vulgaris*). It appears to have lived during the first interglacial epoch, while the Irish elk flourished at a somewhat later geological period. It may possibly, therefore, be regarded as the ancestor of the latter type. The antlers of *M. Ruffii* have fewer "points" or processes than those of *M. hibernicus*; and, although the skull of the animal was as large as or even larger than that of *M. hibernicus*, the antlers were markedly smaller and diverged from one another much less widely than in the case of the latter species. A restoration of the animal accompanies Prof. Nehring's description in *Wild und Hund* for July 10, 1895. From this picture the differences between this new species and *M. hibernicus* may be at once detected.

SOME important experiments of great practical interest have just been published by Dr. Breslauer on the antiseptic properties possessed by disinfectants mixed with different fats in the shape of ointments. As long as fourteen years ago Koch pointed out that carbolic acid combined with olive oil or "carbolised oil," contrary to the prevailing impression, possessed no antiseptic properties. Dr. Breslauer has extended these experiments to an exhaustive examination of various disinfectants, such as carbolic acid, corrosive sublimate, boric acid, nitrate of silver, &c., in combination with oil, vaseline, fat, lanolin anhydricum, lanolin, and unguentum leniens. It was found that the degree of antiseptic power possessed by the disinfectant depended, in a very remarkable manner, upon the particular diluent employed, and that in all cases the best antiseptic results were obtained with disinfectants in combination with lanolin or unguentum leniens. Thus in a series of experiments on the antiseptic effect produced by adding five per cent. of carbolic acid to various substances, it was ascertained that the *Staphylococcus pyogenes aureus* was still living after being immersed in carbolised oil for three days, in carbolised vaselin it survived one day, in fat four hours, in lanolin anhydricum two hours, in lanolin thirty minutes, and in unguentum leniens twenty minutes. Similar results were obtained not only with other bacteria, but also with different disinfectants. Dr. Breslauer has also examined the bactericidal properties of other ointments in frequent use, such as unguentum zinci, unguentum cinereum (benzoatum), and unguentum præcipitatum album, and whilst the two latter were found to be possessed of highly antiseptic properties, the former exercised no perceptible effect whatever. In employing ointments it would appear, therefore, advisable to use the disinfectant selected in combination with lanolin or unguentum leniens instead of supplying vaseline, oil, or other fats, the addition of the latter, according to Dr. Breslauer, serving only to reduce the antiseptic action of the disinfectant. This subject is curiously one which has had, so far, hardly any attention bestowed upon it, and with the exception of some experiments by Gottstein, published in 1889, and, still more recently, an inquiry by Ludwig Bach into the antiseptic effect of various eye ointments, Dr. Breslauer's communication seems to be the only one which has appeared.

WE have recently received two new parts of the *Indian Museum Notes*, from the Trustees of the Museum, being vol. iii. [illegible] 4 [illegible] 5. Part 4 is devoted to an account of the insects and [illegible] the tea-plant in India, and includes full de[illegible], good figures of the principal insects, [illegible] occasionally of their parasites also. The [illegible] the more important plant-feeding orders; but what [illegible] remarkable is the very large number of [illegible] injurious to the tea plant, as compared [illegible]. Thus, only three beetles are mentioned, [illegible], and *Curculionidæ* respectively: as against nineteen *Lepidoptera Heterocera* of various families. The pamphlet concludes with a practical appendix on insecticides. It must not, however, be supposed that a treatise of seventy pages can possibly exhaust the subject of the enemies of any particular plant, especially when they are discussed in detail. A glance at the most important European book on entomological botany (Kaltenbach's "Pflanzenfeinde") is sufficient to show us that many plants are attacked by hundreds of different species of insects; and if this is the case in Europe, it cannot but be true to a still greater extent in tropical countries. But fortunately insects are not always uniformly abundant. They are affected by variations of the season: parasites, and many other influences which are more or less obvious to us; and it is only occasionally that one or other of the numerous species which feed upon any given plant becomes sufficiently abundant to cause any serious injury to it. The other number of the *Indian Museum Notes* before us (part 5) is more varied in its contents. It contains an account of the progress of entomology in the Indian Museum, from 1884–1894, by Mr. E. C. Cotes; some short papers by different entomologists on Indian *Diptera* and *Rhynchota*, and a series of miscellaneous notes on insects of all orders, by Mr. Cotes. This part is not only illustrated, like the other, by numerous woodcuts, but also contains three well-executed plain plates.

THREE important papers by Prof. E. D. Cope, and two by Prof. W. B. Scott, make up, with seven plates, the part recently distributed (vol. ix. part 4) of the *Journal* of the Academy of Natural Sciences of Philadelphia. Prof. Cope treats of new and little known Palæozoic and Mesozoic fishes, and describes Cyphornis—an extinct genus of birds. The genus is established on a species of bird represented by the superior part of a tarsometatarse, obtained by Dr. G. M. Dawson from a bed of indurated greenish clay of unknown age from Vancouver Island. The bird appears to possess real affinities with the Steganopodes, combined with affinities to more primitive birds with a simple hypotarsal structure. "The presumed affinity with the Steganopodes," remarks Prof. Cope, "indicates natatory habits, and probable capacity for flight. Should this power have been developed in *Cyphornis magnus*, it will have been much the largest bird of flight thus far known." Another paper by Prof. Cope is on extinct *Bovidæ*, *Canidæ* and *Felidæ*, from the Pleistocene of Southern Kansas and Western Central Oklahoma. Prof. W. B. Scott's memoir on the structure and relationships of *Ancodus* supplements the extensive investigations of Kowalevsky and Filhol by giving an account of the American species of that genus, and by showing the points of resemblance and differences between the approximately contemporaneous species of *Ancodus* in America and Europe. Prof. Scott concludes his valuable paper as follows:—"With the facts at present known, all seem to point to the origin of *Ancodus* in the Old World and its migration to America, in the interval between the Eocene and the Oligocene (Uinta and White River), yet until the American artiodactyls from the middle and upper Eocene are far better known than at present, such a conclusion cannot be regarded as final." The second paper by Prof. Scott deals with the osteology of *Hyænodon*—a genus described by him in 1877, so far as the materials then available would permit. The Princetown expedition of last year resulted in the collection by Mr. Hatchet of several more or less complete skeletons representing a number of species. These specimens of *Hyænodon* enabled Prof. Scott to supplement the earlier account with the present paper, in which is given a restoration of the skeleton of the very curious and remarkable animal with which it deals.

MESSRS. ROWLAND WARD AND CO., of Piccadilly, are sending out invitations to naturalists to inspect a mounted example of the White Rhinoceros (*Rhinoceros simus*) from Zululand. The

two specimens brought home about two years ago were from Northern Mashonaland. Thus this animal, until lately supposed to be quite extinct, has now been found in a second locality. But these are now the only two spots on the face of the earth where this huge creature, formerly abundant in the Cape Colony, still exists, in very dwindling numbers, which will, no doubt, be now rapidly diminished.

A COMMITTEE of six gentlemen has been appointed by the Governor-General of Goa, India, to carry on excavations in the ancient city of Goa, in rearch of relics of the traditional grandeur of the past, and to take the necessary steps for the preservation of the monuments of Portuguese rule in India in the earlier time.

AN electrical forge, where the whole of the heating required is done by electricity, is in operation at Niagara Falls, the power being supplied by the great cataract. The cost of making a horse-shoe at the electric forge is, it is stated, much less than at an ordinary coal forge. We hear, too, that corn is being threshed by electricity, with very satisfactory results, at Mjolby in Sweden.

WE have received from Mr. W. Radcliffe, of Andreas School, Isle of Man, the inventor of the "Gonagraph," an instrument for drawing perfectly accurate equilateral triangles, squares, pentagons, hexagons, heptagons and octagons, an arithmetical puzzle. The puzzle consists of nineteen small cubes, having a face on each numbered with one of the first nineteen numbers, which are to be placed upon squares, symmetrically arranged on a board, five on the middle row, and two rows of four and three squares to right and left of this. The numbers are to be so arranged that their sum along each of twelve straight lines shall make up thirty-eight. This sum is also obtainable from other symmetrical arangements. It will thus be seen that the puzzle is of the nature of a magic square, and is a very ingenious one. The author has favoured us with his solution, which naturally is at present kept back. He has not furnished us with a clue to his arrangement, and we have in vain searched for it; nor does he say whether he has attempted any extension of the puzzle to thirty-seven or a higher number of cubes. The "thirty-eight" puzzle can be obtained direct from the inventor in a small box for sixpence.

A DESCRIPTION has been sent to us of a new arc lamp for projection purposes, which has been devised by Mr. Cecil M. Hepworth. The instrument has three regulating discs or milled heads of vulcanite, which project at the back, so as to be under the control of the lanternist. The top and bottom discs are for the purpose of regulating the positions of the carbons, and the middle disc has three duties to perform, viz. to bring the carbons slowly together as their points waste in consumption, by a push action to cause the carbons instantaneously to touch, and by a spring to as quickly separate, while by an upward movement the worm-wheel is thrown completely out of gear, and the carbons can be rapidly separated or brought together by hand, a provision necessary for the saving of time when inserting new carbons.

THE September part of the *Proceedings* of the Physical Society of London has reached us, and contains, in addition to the usual valuable supplement of "Abstracts of Physical Papers from Foreign Sources," the following papers:—"A Theory of the Synchronous Motor," by W. G. Rhodes (continuation); "On the Use of an Iodine Voltameter for the Measurement of Small Currents," by Prof. E. F. Herroun, "On the Condensation and the Critical Phenomena of Mixtures of Ethane and Nitrous Oxide," by Dr. Kuenen; "An Electro-Magnetic Effect," by F. W. Bowden; and "The Electrical Properties of Selenium," by Shelford Bidwell, F.R.S.

THE September-October part of the *Physical Review* (Macmillan) contains the following articles: "A Study of the Polarisation of the Light emitted by Incandescent Solid and Liquid Surfaces," by R. A. Millikan, "Alternating Currents when the Electromotive Force is of a Zigzag Wave Type," by E. C. Rimmington, "On Ternary Mixtures," by W. D. Bancroft, part 2; and minor contributions.

BOURNE's Handy Assurance Manual for 1895, by William Schooling, has been published. It contains in a small compass a whole host of information likely to be of use to those who are interested in insurance matters, and appears to have been compiled with great care.

WE have received from Messrs. G. W. Wilson and Co., Limited, 2 St. Swithin Street, Aberdeen, copies of their catalogues of lantern slides. The list of subjects illustrated is a very full one, and the catalogues may be had upon application.

ON the completion of the fiftieth year of its existence, the editor of the *Botanische Zeitung* publishes a very useful index of the papers contained in the first fifty volumes.

THE September number of the *Irish Naturalist* has just appeared, and is entirely devoted to reports of the Galway conference and excursion of the Irish Field Club Union, held in July.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by Miss Larkin; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mr. W. Aldridge; a Purple-faced Monkey (*Semnopithecus leucoprymnus*) from Ceylon, presented by Mrs. Griffith; a —— Monkey (*Cercopithecus*, sp. inc.) from Africa, presented by Miss Pigott; two Vulpine Phalangers (*Phalangista vulpina*, ♂ ♀) from Australia, presented by Mr. F. J. Horniman; a Magpie (*Pica caudata*), British, presented by Mr. H. E. Blandford; an Orange-cheeked Amazon (*Chrysotis autumnalis*) from Central America, presented by the Rev. W. J. Loftie; a Martinique (*Ionornis martinicus*), captured off the Island of Ascension, presented by Mr. H. W. Power; a Smooth Snake (*Coronella lævis*), a Common Viper (*Vipera berus*), British, presented by Mr. G. J. S. Warner; a Brown Capuchin (*Cebus fatuellus*) from Guiana, three Grant's Francolines (*Francolinus granti*) from East Africa, two Egyptian Trionyx (*Trionyx niloticus*) from the Congo, deposited; a Two-toed Sloth (*Cholopus didactylus*) from Brazil, a Yellow-naped Amazon (*Chrysotis auripalliata*) from Central America, purchased.

OUR ASTRONOMICAL COLUMN.

THE ORBIT OF μ^2 BOOTIS (Σ 1938).—Dr. T. J. J. See gives in the *Astr. Nach.*, No. 3309, Bd. 138, the results of his researches on this star. This double was discovered by Sir William Herschel in 1781, and since the time of Struve it has been very abundantly observed. In all parts of the orbit the pair is sufficiently wide to be seen with a 6-inch telescope. The investigation gives the following elements of μ^2 Bootis; other elements are given for comparison.

The apparent orbit is:

$$\text{Major axis} = 2''.656$$
$$\text{Minor axis} = 1''.480$$
$$\text{Angle of major axis} = 173^\circ.5$$
$$\text{,, \ ,, periastron} = 186^\circ.7$$
$$\text{Distance of star from centre} = 0''.038$$

The computed and observed places seem to justify the new elements given above. The period thus will hardly be varied by as much as ten years, while the resulting alteration will be small in proportion.

THE BRITISH ASSOCIATION.

SECTION K.

BOTANY.

OPENING ADDRESS BY W. T. THISELTON-DYER, M.A., F.R.S., C.M.G., C.I.E., DIRECTOR OF THE ROYAL GARDENS.

THE establishment of a new Section of the British Association, devoted to Botany, cannot but be regarded by the botanists of this country as an event of the greatest importance. For it is practically the first time that they have possessed an independent organisation of their own. It is true that for some years past we have generally been strong enough to form a separate department of the old Biological Section D, on the platform of which so many of us in the past have acted in some capacity or other, and on which indeed many of us may be said to have made our first appearance. We shall not start then on our new career without the remembrance of filial affection for our parent, and the earnest hope that our work may be worthy of its great traditions.

The first meeting of the Section, or, as it was then called, Committee, at Oxford was held in 1832. And though there has been from time to time some difference in the grouping of the several biological sciences, the two great branches of biology have only now for the first time formally severed the partnership into which they entered on that occasion. That this severance, if inevitable from force of circumstances, is in some respects a matter of regret, I do not deny. Specialisation is inseparable from scientific progress; but it will defeat its own end in biology if the specialist does not constantly keep in touch with those fundamental principles which are common to all organic nature. We shall have to take care that we do not drift into a position of isolation. Section D undoubtedly afforded a convenient opportunity for discussing many questions on which it was of great advantage that workers in the two different fields should compare their results and views. But I hope that by means of occasional conferences we shall still, in some measure, be able to preserve this advantage.

RETROSPECT.

I confess I found it a great temptation to review, however imperfectly, the history and fortunes of our subject while it belonged to Section D. But to have done so would have been practically to have written the history of botany in this country since the first third of the century. Yet I cannot pass over some few striking events.

I think that the earliest of these must undoubtedly be regarded as the most epoch-making. I mean the formal publication by the Linnean Society, in 1833, of the first description of "the nucleus of the cell," by Robert Brown ("Misc. Bot. Works," i. 512). It seems difficult to realise that this may be within the recollection of some who are now living amongst us. It is, however, of peculiar interest to me that the first person who correctly distinguished this all-important body, and indicated it in a figure, was Francis Bauer, thirty years earlier, in 1802. This remarkable man, whose skill in applying the resources of art to the illustration of plant anatomy has never, I suppose been surpassed, was "resident draughtsman for fifty years to the Royal Botanic Garden at Kew." And it was at Kew, and in a flower of *Phajus grandifolius*, no doubt grown there, that the discovery was made.

It must be confessed, with no little admiration that, on refreshing my memory by a reference to Robert Brown's paper, I read again the vivid account which he gives in a footnote of the phenomena, so painfully familiar to many of us who have been taught, of circulation in the staminal hair of *Tradescantia*. Sir Joseph Hooker (*Proc. Linn. Soc.*, 1887-88, 65) has well remarked that "the supreme importance of this observation. . . . leading to undreamt-of conceptions of the fundamental phenomena of organic life, is acknowledged by all investigators." It is singular that so profound an observer as Robert Brown should have himself missed the significance of what he saw. The world had to wait for the discovery of protoplasm by Von Mohl till 1846, and till 1850 for its identification with the sarcode of zoologists by Cohn, who is still, I am happy to say, living and at work, and to whom last year the Linnean Society did itself the honour of presenting its medal.

The Edinburgh meeting of the Association, in 1834, was the occasion of the announcement of another memorable discovery of Robert Brown's. I will content myself with quoting Hofmeister's ("Higher Cryptogamia," 432) account of it. "Robert Brown was the discoverer of the polyembryony of the *Coniferæ*. In a later treatise he pointed out the origin of the pro-embryo in large cells of the endosperm, to which he gave the name of corpuscula." The period of the forties, just half a century ago, looks in the retrospect as one of almost dazzling discovery. To say nothing of the formal appearance of protoplasm on the scene, the foundations were being laid in all directions of our modern botanical morphology. Yet its contemporaries viewed it with a very philosophical calm. Thwaites, who regarded Carpenter as his master, described at the Oxford meeting in 1847 the conjugation of the *Diatomaceæ*, and "distinctly indicated," as Carpenter ("Memorial Sketch," 140) says, "that conjugation is the primitive phase of sexual reproduction." Berkeley informed me that the announcement fell perfectly flat. A year or two later Suminski came to London with his splendid discovery (1848) of the archegonia of the fern, the antheridia having been first seen by Nägeli in 1844. Carpenter (*loc. cit.*, 141) gave me, many years after, a curious account of its reception. "At the Council of the Ray Society, at which," he said, "I advocated the reproduction of Suminski's book on the 'Ferns,' I was assured that the close resemblance of the antherozoids to spermatozoa was quite sufficient proof that they could have nothing to do with vegetable reproduction. I do not think," he added—and the complaint is pathetic—"that the men of the present generation, who have been brought up in the *light*, quite apprehend (in this as in other matters) the utter darkness in which we were then groping, or fully recognise the deserts of those who helped them to what they now enjoy." This was in 1875, and I suppose is not likely to be less true now.

The Oxford meeting in 1860 was the scene of the memorable debate on the origin of species, at which it is interesting to remember that Henslow presided. On that occasion Section D reached its meridian. The battle was Homeric. However little to the taste of its author, the launching of his great theory was, at any rate, dignified with a not inconsiderable explosion. It may be that it is not given to the men of our day to ruffle the dull level of public placidity with disturbing and far-reaching ideas. But if it were, I doubt whether we have, or need now, the fierce energy which inspired then either the attack or the defence. When we met again in Oxford last year the champion of the old conflict stood in the place of honour, acclaimed of all men, a beautiful and venerable figure. We did not know then that that was to be his farewell.

The battle was not in vain. Six years afterwards, at Nottingham, Sir Joseph Hooker delivered his classical lecture on Insular Floras. It implicitly accepted the new doctrine, and applied it with admirable effect to a field which had long waited for an illuminating principle The lecture itself has since remained one of the corner-stones of that rational theory of the geographical distribution of plants which may, I think, be claimed fairly as of purely English origin.

HENSLOW.

Addressing you as I do at Ipswich, there is one name written in the annals of our old Section which I cannot pass over—that of Henslow. He was the Secretary of the Biological Section at its first meeting in 1832, and its President at Bristol in 1836. I suppose there are few men of this century who have indirectly more influenced the current of human thought. For in great measure I think it will not be contested that we owe Darwin to him. As Romanes has told us ("Memorial Notices," 13): "His letters written to Prof. Henslow during his voyage round the world overflow with feelings of affection, veneration, and obligation to his accomplished master and dearest friend—feelings which throughout his life he retained with no diminished intensity. As he used himself to say, before he knew Prof.

Henslow the only objects he cared for were foxes and partridges." I do not wish to overstate the facts. The possession of "the collector's instinct, strong in Darwin from his childhood, as is usually the case in great naturalists," to use Huxley's (*Proc. R.S.*, xliv. vi.) words, would have borne its usual fruit in after life, in some shape or other, even if Darwin had not fallen into Henslow's hands. But then the particular train of events which culminated in the great work of his life would never have been started. It appeared to me, then, that it would not be an altogether uninteresting investigation to ascertain something about Henslow himself. The result has been to provide me with several texts, which I think it may be not unprofitable to dwell upon on the present occasion.

In the first place, what was the secret of his influence over Darwin? "My dear old master in Natural History" ("Life," ii. 317) he calls him; and to have stood in this relation to Darwin[1] is no small matter. Again, he speaks of his friendship with him as "a circumstance which influenced my whole career more than any other" (i. 52). The singular beauty of Henslow's character, to which Darwin himself bore noble testimony, would count for something, but it would not in itself be a sufficient explanation. Nor was it that intellectual fascination which often binds pupils to the master's feet; for, as Darwin tells us, "I do not suppose that any one would say that he possessed much original genius" (i. 52). The real attraction seems to me to be found in Henslow's possession, in an extraordinary degree, of what may be called the Natural History spirit. This resolves itself into keen observation and a lively interest in the facts observed. "His strongest taste was to draw conclusions from long-continued minute observations" (i. 52). The old Natural History method, of which it seems to me that Henslow was so striking an embodiment, is now, and I think unhappily, almost a thing of the past. The modern university student of botany puts his elders to blush by his minute knowledge of some small point in vegetable histology. But he can tell you little of the contents of a country hedgerow; and if you put an unfamiliar plant in his hands he is pretty much at a loss how to set about recognising its affinities. Disdaining the field of nature spread at his feet in his own country, he either seeks salvation in a German laboratory or hurries off to the Tropics, convinced that he will at once immortalise himself. But *cælum non animum mutat*; he puts into "pickle" the same objects as his predecessors, never to be looked at again; or perhaps writes a paper on some obvious phenomena which he could have studied with less fatigue in the Palm House at Kew.

The secret of the right use of travel is the possession of the Natural History instinct, and to those who contemplate it I can only recommend a careful study of Darwin's "Naturalist's Voyage." Nothing that came in his way seems to have evaded him or to have seemed too inconsiderable for attention. No doubt some respectable travellers have lost themselves in a maze of observations that have led to nothing. But the example of Darwin, and I might add of Wallace, of Huxley, and of Moseley, show that that result is the fault of the man and not of the method. The right moment comes when the fruitful opportunity arrives to him who can seize it. The first strain of the prelude with which the "Origin" commences are these words: "When on board H.M.S. *Beagle* as naturalist, I was much struck with certain facts in the distribution of the organic beings inhabiting South America." But this sort of vein is not struck at hazard or by him who has not served a tolerably long apprenticeship to the work.

When one reads and re-reads the "Voyage," it is simply amazing to see how much could be achieved with a previous training which we now should think ludicrously inadequate. Before Henslow's time the state of the natural sciences at Cambridge was incredible. In fact, Leonard Jenyns ("Memoir," 175), his biographer, speaks of the "utter disregard paid to Natural History in the University previous to his taking up his residence there." The Professor of Botany had delivered no lectures for thirty years, and though Sir James Smith, the founder of the Linnean Society, had offered his services, they were declined on the ground of his being a Nonconformist (*ibid.*, 37).

As to Henslow's own scientific work, I can but rely on the judgment of whose who could appreciate it in relation to its time. According to Berkeley (*ibid.*, 56), "he was certainly one of the first, if not the very first, to see that two forms of fruit might exist in the same fungus." And this, as we now know, was a fundamental advance in this branch of morphology. Sir Joseph Hooker tells me that his papers were all distinctly in advance of his day. Before occupying the chair of botany, he held for some years that of mineralogy. Probably he owed this to his paper on the Isle of Anglesey, published when he was only twenty-six. I learn from the same authority, that this to some extent anticipated, but at any rate strongly influenced, Sedgwick's subsequent work in the same region.

Botanical Teaching.

Henslow's method of teaching deserves study. Darwin says of his lectures "that he liked them much for their extreme clearness." "But," he adds, "I did not study botany" (i. 48). Yet we must not take this too seriously. Darwin ("Voyage," 421), when at the Galapagos, "indiscriminately collected every thing in flower on the different islands, and fortunately kept my collections separate." Fortunately indeed; for it was the results extracted from these collections, when worked up subsequently by Sir Joseph Hooker, which determined the main work of his life. "It was such cases as that of the Galapagos Archipelago which chiefly led me to study the origin of species" (iii. 159).

Henslow's actual method of teaching went some way to anticipate the practical methods of which we are all so proud. "He was the first to introduce into the botanical examination for degrees in London the system of practical examination" ("Memoir," 161). But there was a direct simplicity about his class arrangements characteristic of the man. "A large number of specimens . . . were placed in baskets on a side-table in the lecture-room, with a number of wooden plates and other requisites for dissecting them after a rough fashion, each student providing himself with what he wanted before taking his seat" (*ibid.*, 39). I do not doubt that the results were, in their way, as efficient as we obtain now in more stately laboratories.

The most interesting feature about his teaching was not, however, its academic aspect, but the use he made of botany as a general educational instrument. "He always held that a man of *no* powers of observation was quite an exception" (*ibid.*, 163). He thought (and I think he proved) that botany might be used "for strengthening the observant faculties and expanding the reasoning powers of children in all classes of society" (*ibid.*, 99). The difficulty with which those who undertake now to teach our subject have to deal is that most people ask the question, What is the use of learning botany unless one means to be a botanist? It might indeed be replied that as the vast majority of people never learn anything effectively, they might as well try botany as anything else. But Henslow looked only to the mental discipline; and it was characteristic of the man and of his belief in his methods that when he was summoned to Court to lecture to the Royal family, his lectures "were, in all respects, identical with those he was in the habit of giving to his little Hitcham scholars" ("Memoir," 149); and it must be added that they were not less successful.

This success naturally attracted attention. Botanical teaching in schools was taken up by the Government, and continues to receive support to the present day. But the primitive spirit has, I am afraid, evaporated. The measurement of results by means of examination has been fatal to its survival. The teacher has to keep steadily before his eyes the necessity of earning his grant. The educational problem retires into the background. "The strengthening of the observant faculties," and the rest of the Henslowian programme must give way to the imperious necessity of presenting to the examiner candidates equipped with at least the minimum of text-book formulas reproducible on paper. I do not speak in this matter without painful experience. The most astute examiner is defeated by the still more astute crammer. The objective basis of the study on which its whole usefulness is built up is promptly thrown aside. If you supply the apple blossom for actual description, you are as likely as not to be furnished with a detailed account of a buttercup. The training of observation has gone by the board, and the exercise of mere memory has taken its place. But a table of logarithms or a Hebrew grammar would serve this purpose equally well. Yet I do not despair of Henslow's work still bearing fruit. The examination system will collapse from the sheer impossibility of carrying it on beyond a certain point. Freed from its trammels, the teacher will have greater scope for individuality, and the result of his labours will be rewarded after some intelligent system of inspection. And here I may claim support from an unexpected quarter. Mr. Gladstone has recently written to a

[1] As I shall have frequent occasion to quote the "Life and Letters" I shall insert the references in the text.

[illegible]: "I think that the neglect of natural history, in all its multitude of branches, was the grossest defect of our old system of training for the young: and, further, that little or nothing has been done by way of remedy for that defect in the attempts made to alter or reform that system." I am sure that the importance and weight of this testimony, coming as it does from one whose training and sympathies have always been literary, cannot be denied. That there is already some revival of Henslow's methods, I judge from the fact that I have received applications from Board Schools, amounting to some hundreds, for surplus specimens from the Kew Museums. Without a special machinery for the purpose I cannot do much, and perhaps it is well. But my staff have willingly done what was possible, and from the letters I have received I gather that the labour has not been wholly misspent.

MUSEUM ARRANGEMENT.

This leads me to the last branch of Henslow's scientific work which I am able to touch, that of the arrangement of museums, especially those which being local have little meaning unless their purpose is strictly educational. I think it is now generally admitted that, both in the larger and narrower aspects of the question, his ideas, which were shared in some measure by Edward Forbes, were not merely far in advance of his time, but were essentially sound. And here I cannot help remarking that the zoologists have perhaps profited more by his teaching than the botanists. I do not know how far Sir William Flower and Prof. Lankester would admit the influence of Henslow's ideas. But, so far as my knowledge goes, I am not aware that, at any rate in Europe, there is anything to be seen in public museums comparable to the educational work accomplished by the one at the College of Surgeons and the Natural History Museum, and by the other at Oxford.

I have often thought it singular that in botany we have not kept pace in this matter with our brother naturalists. I do not doubt that vegetable morphology and a vast number of important facts in evolution, as illustrated from the vegetable kingdom, might be presented to the eye in a fascinating way in a carefully arranged museum. The most successful and, indeed, almost the only attempt which has been made in this direction is that at Cambridge, which, I believe, is due to Mr. Gardiner. But our technical methods for preserving specimens still leave much to desire. Something more satisfactory will, it may be hoped, some day be devised, and the whole subject is one which is well worth the careful consideration of our Section. Henslow at least effected a vast improvement in the mode of displaying natural objects; and a collection prepared by his own hands, which was exhibited at one of the Paris exhibitions, excited the warm admiration of the French botanists, who always appreciate the clear illustration of morphological facts.

OLD SCHOOL OF NATURAL HISTORY.

If the old school of natural history of which Henslow in his day was a living spirit is at present, as seems to be the case, continually losing its hold upon us, this has certainly not been due to its want of value as an educational discipline, or to its sterility in contributing new ideas to human knowledge. Darwin's "Origin of Species" may certainly be regarded as its offspring, and of this Huxley (*Proc. R.S.*, xliv. xvii.) says with justice: "It is doubtful if any single book except the 'Principia,' ever worked so great and rapid a revolution in science, or made so deep an impression on the general mind." Yet Darwin's biographer, in that admirable "Life" which ranks with the few really great biographies in our language, remarks (i. 155): "In reading [illegible] books one is reminded of the older naturalists rather than of the modern school of writers. He was a naturalist in the old sense of the word, that is, a man who works at many [illegible], not merely a specialist in one." This is no [illegible] but [illegible] not exactly hit off the distinction between the [illegible] study which has gone out of fashion and that which [illegible]. The older workers in biology were occupied [illegible] with the external or, at any rate, grosser features of [illegible] relation to surrounding conditions; the [illegible] on the other hand, are engaged on the study of internal [illegible]. Work in the laboratory, with its neces[illegible] the place of research in the field. One [illegible] that the use of the compound microscope [illegible]. Asa Gray has compared Robert Brown with Darwin [illegible] British naturalists who have "more [illegible] their influence upon science in the nineteenth century" (NATURE, x. 80). Now it is noteworthy that Robert Brown did all his work with a simple microscope. And Francis Darwin writes of his father: "It strikes us nowadays as extraordinary that he should have had no compound microscope when he went his *Beagle* voyage; but in this he followed the advice of Robert Brown, who was an authority on such matters" (i. 145). One often meets with persons, and sometimes of no small eminence, who speak as if there were some necessary antagonism between the old and the new studies. Thus I have heard a distinguished systematist describe the microscope as a curse, and a no less distinguished morphologist speak of a herbarium having its proper place on a bonfire. To me I confess this anathematisation of the instruments of research proper to any branch of our subject is not easily intelligible. Yet in the case of Darwin himself it is certain that if his earlier work may be said to rest solely on the older methods, his later researches take their place with the work of the new school. At our last meeting Pfeffer vindicated one of his latest and most important observations.

The case of Robert Brown is even more striking. He is equally great whether we class him with the older or the modern school. In fact, so far as botany in this country is concerned, he may be regarded as the founder of the latter. It is to him that we owe the establishment of the structure of the ovule and its development into the seed. Even more important were the discoveries to which I have already referred, which ultimately led to the establishment of the group of Gymnosperms. "No more important discovery," says Sachs ("History," 142), "was ever made in the domain of comparative morphology and systematic botany. The first steps towards this result, which was clearly brought out by Hofmeister twenty-five years later, were secured by Robert Brown's researches, and he was incidentally led to these researches by some difficulties in the construction of the seed of an Australian genus." Yet it may be remembered that he began his career as naturalist to Flinders's expedition for the exploration of Australia. He returned to England with 4000 "for the most part new species of plants." And these have formed the foundation of our knowledge of the flora of that continent. Brown's chief work was done between 1820 and 1840, and, as Sachs (*loc. cit.*, 139, 140) tells us, "was better appreciated during that time in Germany than in any other country."

MODERN SCHOOL.

The real founder of the modern teaching in this country in both branches of biology I cannot doubt was Carpenter. The first edition of his admirable "Principles of Comparative Physiology" was published in 1838, the last in 1854. All who owe, as I do, a deep debt of gratitude to that book will agree with Huxley ("Memorial Sketch," 67) in regarding it as "by far the best general survey of the whole field of life and of the broad principles of biology which had been produced up to the time of its publication. Indeed," he adds, "although the fourth edition is now in many respects out of date, I do not know its equal for breadth of view, sobriety of speculation, and accuracy of detail."

The charm of a wide and philosophic survey of the different forms under which life presents itself could not but attract the attention of teachers. Rolleston elaborated a course of instruction in zoology at Oxford in which the structures described in the lecture-room were subsequently worked out in the laboratory. In 1872 Huxley organised the memorable course in elementary biology at South Kensington which has since, in its essential features, been adopted throughout the country. In the following year, during Huxley's absence abroad through ill-health, I arranged, at his request, a course of instruction on the same lines for the Vegetable Kingdom.

That the development of the new teaching was inevitable can hardly be doubted, and I for my part am not disposed to regret the share I took in it. But it was not obvious, and certainly it was not expected, that it would to so large an extent cut the ground from under the feet of the old Natural History studies. The consequences are rather serious, and I think it is worth while pointing them out.

In a vast empire like our own there is a good deal of work to be done and a good many posts to be filled, for which the old Natural History training was not merely a useful but even a necessary preparation. But at the present time the universities almost entirely fail to supply men suited to the work. They neither care to collect, nor have they the skilled aptitude for

observation. Then, though this country is possessed at home of incomparable stores of accumulated material, the class of competent amateurs who were mostly trained at our universities, and who did such good service in working that material out, is fast disappearing. It may not be easy indeed in the future to fill important posts even in this country with men possessing the necessary qualifications. But there was still another source of naturalists, even more useful, which has practically dried up. It is an interesting fact that the large majority of men of the last generation who have won distinction in this field have begun their career with the study of medicine. That the kind of training that Natural History studies give is of advantage to students of medicine which, rightly regarded, is itself a Natural History study, can hardly be denied. But the exigencies of the medical curriculum have crowded them out; and this, I am afraid, must be accepted as irremediable. I cannot refrain from reading you, on this point, an extract from a letter which I have received from a distinguished official lately entrusted with an important foreign mission. I should add that he had himself been trained in the old way.

"I have had my time, and must leave to younger men the delight of working these interesting fields. Such chances never will occur again, for roads are now being made and ways cut in the jungle and forest, and you have at hand all sorts of trees level on the ground ready for study. These bring down with them orchids, ferns, and climbers of many kinds, including rattan palms, &c. But, excellent as are the officers who devote their energy to thus opening up this country, there is not one man who knows a palm from a dragon-tree, so the chance is lost. Strange to say, the medical men of the Government service know less and care less for Natural History than the military men, who at least regret they have no training or study to enable them to take an intelligent interest in what they see around them. A doctor nowadays cares for no living thing larger or more complicated than a *bacterium* or a *bacillus*."

But there are other and even more serious grounds why the present dominance of one aspect of our subject is a matter for regret. In the concluding chapter of the "Origin," Darwin wrote: "I look with confidence to the future—to young and rising naturalists." But I observe that most of the new writers on the Darwinian theory, and, oddly enough, especially when they have been trained at Cambridge, generally begin by more or less rejecting it as a theory of the origin of species, and then proceed unhesitatingly to reconstruct it. The attempt rarely seems to me successful, perhaps because the limits of the laboratory are unfavourable to the accumulation of the class of observations which are suitable for the purpose. The laboratory, in fact, has not contributed much to the Darwinian theory, except the "Law of Recapitulation," and that, I am told, is going out of fashion.

The Darwinian theory, being, as I have attempted to show, the outcome of the Natural History method, rested at every point on a copious basis of fact and observation. This more modern speculation lacks. The result is a revival of transcendentalism. Of this we have had a copious crop in this country, but it is quite put in the shade by that with which we have been supplied from America. Perhaps the most remarkable feature is the persistent vitality of Lamarckism. As Darwin remarks: "Lamarck's one suggestion as to the cause of the gradual modification of species—effort excited by change of conditions—was, on the face of it, inapplicable to the whole vegetable world" (ii. 189). And if we fall back on the inherited direct effect of change of conditions, though Darwin admits that "physical conditions have a more direct effect on plants than on animals" (ii. 319), I have never been able to convince myself that that effect is inherited. I will give one illustration. The difference in habit of even the same species of plant when grown under mountain and lowland conditions is a matter of general observation. It would be difficult to imagine a case of "acquired characters" more likely to be inherited. But this does not seem to be the case. The recent careful research of Gaston Bonnier only confirms the experience of cultivators. The modifications acquired by the plant when transported for a definite time from the plains to the Alps, or *vice versâ*, disappear at the end of the same period when the plant is restored to its original conditions (*Ann. d. S. nat.*, 7e sér. xx. 355).

Darwin, in an eloquent passage, which is too long for me to quote ("Origin," 426), has shown how enormously the interest of Natural History is enhanced "when we regard every production of nature as one which has had a long history," and "when we contemplate every complex structure . . . as the summing up of many contrivances." But this can only be done, or at any rate begun, in the field, and not in the laboratory.

A more serious peril is the dying out amongst us of two branches of botanical study in which we have hitherto occupied a position of no small distinction. Apart from the staffs of our official institutions, there seems to be no one who either takes any interest in, or appreciates in the smallest degree, the importance of systematic and descriptive botany. And geographical distribution is almost in a worse plight, yet Darwin calls it, "that grand subject, that almost keystone of the laws of creation" (i. 356).

I am aware that it is far easier to point out an evil than to remedy it. The teaching of botany at the present day has reached a pitch of excellence and earnestness which it has never reached before. That it is somewhat one-sided cannot probably be remedied without a subdivision of the subject and an increase in the number of teachers. If it has a positive fault, it is that it is sometimes inclined to be too dogmatic and deductive. Like Darwin, at any rate in a biological matter, "I never feel convinced by deduction, even in the case of H. Spencer's writings" (iii. 168). The intellectual indolence of the student inclines him only too gladly to explain phenomena by referring them to "isms," instead of making them tell their own story.

ORGANISATION OF SECTION.

I am afraid I have detained you too long over these matters, on which I must admit I have spoken with some frankness. But I take it that one of the objects of our Section is to deliver our minds of any perilous stuff that is fermenting in it. But now, having taken leave of the past, let us turn to the future.

We start at least with a clean slate. We cannot bind our successors, it is true, at other meetings. But I cannot doubt that it will be in our power to materially shape our future, notwithstanding. When we were only a department I think we all felt the advantage of these annual meetings, of the profitable discussion, formal and informal, and of the privilege of meeting so many of our foreign brethren who have so generously supported us by their presence and sympathy.

I am anxious, then, to suggest that we should conduct our proceedings on as broad lines as possible. I do not think we should be too ready to encourage papers which may well be communicated to societies, either local or central.

The field is large; the labourers as they advance in life can hardly expect to keep pace with all that is going on in it. We must look to individual members of our number to help us by informing and stimulating addresses on subjects they have made peculiarly their own, or on important researches on which they have been specially engaged.

NOMENCLATURE.

There is one subject upon which, from my official position elsewhere, I desire to take the opportunity of saying a few words. It is that of Nomenclature. It is not on its technical side, I am afraid, of sufficient general interest to justify my devoting to it the space which its importance would otherwise deserve. But I hope to be able to enlist your support for the broad common-sense principles on which our practice should rest.

As I suppose, every one knows we owe our present method of nomenclature in natural history to Linnæus. He devised the binominal, or, as it is often absurdly called, the binomial system. That we must have a technical system of nomenclature I suppose no one here will dispute. It is not, however, always admitted by popular writers who have not appreciated the difficulty of the matter, and who think all names should be in the vernacular. There is the obvious difficulty that the vast majority of plants do not possess any names at all, and the attempts to manufacture them in a popular shape have met with but little success. Then, from lack of discriminating power on the part of those who use them, vernacular names are often ambiguous; thus Bullrush is applied equally to *Typha* and to *Scirpus*, plants extremely different. Vernacular names, again, are only of local utility, while the Linnean system is intelligible throughout the world.

A technical name, then, for a plant or animal is a necessity, as without it we cannot fix the object of our investigations into its affinity, structure, or properties ("Linn. Phil.," 210). "Nomina si nescis perit et cognito rerum.

In order to get clear ideas on the matter let us look at the

logical principles on which such names are based. It is fortunate for us that these are stated by Mill, who, besides being an authority on logic, was also an accomplished botanist. He tells us ("System of Logic," i. 132): "A naturalist, for purposes connected with his particular science, sees reason to distribute the animal or vegetable creation into certain groups rather than into any others, and he requires a name to bind, as it were, each of his groups together." He further explains that such names, whether of species, genera, or orders, are what logicians call connotative; they *denote* the members of each group, and *connote* the distinctive characters by which it is defined. A species, then, connotes the common characters of the individuals belonging to it; a genus, those of the species; an order, those of the genera.

But these are the logical principles, which are applicable to names generally. A name such as *Ranunculus repens* does not differ in any particular from a name such as John Smith, except that one denotes a species, the other an individual.

This being the case, and technical names being a necessity, they continually pass into general use in connection with horticulture, commerce, medicine, and the arts. It seems obvious that, if science is to keep in touch with human affairs, stability in nomenclature is a thing not merely to aim at, but to respect. Changes become necessary, but should never be insisted upon without grave and solid reason. In some cases they are inevitable unless the taxonomic side of botany is to remain at a standstill. From time to time the revision of a large group has to be undertaken from a uniform and comparative point of view. It then often occurs that new genera are seen to have been too hastily founded on insufficient grounds, and must therefore be merged in others. This may involve the creation of a large number of new names, the old ones becoming henceforth a burden to literature as synonyms. It is usual in such cases to retain the specific portion of the original name, if possible. If it is, however, already preoccupied in the genus to which the transference is made, a new one must be devised. Many modern systematists have, however, set up the doctrine that a specific epithet once given is indelible, and whatever the taxonomic wanderings of the organism to which it was once assigned, it must always accompany it. This, however, would not have met with much sympathy from Linnæus, who attached no importance to the specific epithet at all: "Nomen specificum sine generico est quasi pistillum sine campana" ("Phil.," 219). Linnæus always had a solid reason for everything he did or said, and it is worth while considering in this case what it was.

Before his time the practice of associating plants in genera had made some progress in the hands of Tourneford and others, but specific names were still cumbrous and practically unusable. Genera were often distinguished by a single word; and it was the great reform accomplished by Linnæus to adopt the binominal principle for species. But there is this difference. Generic names are unique, and must not be applied to more than one distinct group. Specific names might have been constituted on the same basis: the specific name in that case would then have never been used to designate more than one plant, and would have been sufficient to indicate it. We should have lost, it is true, the useful information which we get from our present practice in learning the genus to which the species belongs; but theoretically a nomenclature could have been established on the one name principle. The thing, however, is impossible now even if it were desirable. A specific epithet like *vulgaris* may belong to hundreds of different species belonging to as many different genera, and taken alone is meaningless. A Linnean name, then, though it consists of two parts, must be treated as a whole. "Nomen omne plantarum constabit nomine generico et specifico" ("Phil." 212). A fragment can have no vitality of its own. Consequently, if superseded, it may be replaced by another which may be perfectly independent.[1]

It constantly happens that the same species is named and described by more than one writer, or different views are taken of specific differences by various writers; the species of one are therefore "lumped" by another. In such cases, where there is a choice of names, it is customary to select the earliest published. I agree, however, with the late Sereno Watson (NATURE, xlvi. 54) that "there is nothing whatever of an ethical character inherent in a name, through any priority of publication or position, which should render it morally obligatory upon any one to accept one name rather than another." And in point of fact Linnæus and the early systematists attached little importance to priority. The rigid application of the principle involves the assumption that all persons who describe or attempt to describe plants are equally competent to the task. But this is far from being the case that it is sometimes all but impossible even to guess what could possibly have been meant.[1]

In 1872 Sir Joseph Hooker ("Flora of British India," i. vii.) wrote: "The number of species described by authors who cannot determine their affinities increases annually, and I regard the naturalist who puts a described plant into its proper position in regard to its allies as rendering a greater service to science than its describer when he either puts it into a wrong place or throws it into any of those chaotic heaps, miscalled genera, with which systematic works still abound." This has always seemed to me not merely sound sense, but a scientific way of treating the matter. What we want in nomenclature is the maximum amount of stability and the minimum amount of change compatible with progress in perfecting our taxonomic system. Nomenclature is a means, not an end. There are perhaps 150,000 species of flowering plants in existence. What we want to do is to push on the task of getting them named and described in an intelligible manner, and their affinities determined as correctly as possible. We shall then have material for dealing with the larger problems which the vegetation of our globe will present when treated as a whole. To me the botanists who waste their time over priority are like boys who, when sent on an errand, spend their time in playing by the roadside. By such men even Linnaeus is not to be allowed to decide his own names. To one of the most splendid ornaments of our gardens he gave the name of *Magnolia grandiflora*: this is now to be known as *Magnolia fœtida*. The reformer himself is constrained to admit, "The change is a most unfortunate one in every way" ("Garden and Forest," ii. 615). It is difficult to see what is gained by making it, except to render systematic botany ridiculous. The genus *Aspidium*, known to every fern cultivator, was founded by Swartz. It now contains some 400 species, of which the vast majority were, of course, unknown to him at the time: yet the names of all these are to be changed because Adamson founded a genus, *Dryopteris*, which seems to be the same thing as *Aspidium*. What, it may be asked, is gained by the change? To science it is certainly nothing. On the other hand, we lumber our books with a mass of synonyms, and perplex every one who takes an interest in ferns. It appears that the name of the well-known Australian genus *Banksia* really belongs to *Pimelea*; the species are therefore to be renamed, and *Banksia* is to be rechristened *Sirmuellera*, after Sir Ferdinand von Mueller: a proposal which, I need hardly say, did not emanate from an Englishman.

I will not multiply instances. But the worst of it is that those who have carefully studied the subject know that, from various causes which I cannot afford the time to discuss, when once it is attempted to disturb accepted nomenclature it is almost impossible to reach finality. Many genera only exist by virtue of their redefinition in modern times; in the form in which they were originally promulgated they have hardly any intelligible meaning at all.

It can hardly be doubted that one cause of the want of attention which systematic botany now receives is the repulsive labour of the bibliographical work with which it has been overlaid. What an enormous bulk nomenclature has already attained may be judged from the "Index Kewensis," which was prepared at Kew, and which we owe to the munificence of Mr. Darwin. In his own studies he constantly came on the track of names which he was unable to run down to their source. This the "Index" enables to be done. It is based, in fact, on a manuscript index which we compiled for our own use at Kew. But it is a mistake to suppose that it is anything more than the name signifies, or that it expresses any opinion as to the validity of the names themselves. That those who use the book must judge of for themselves. We have indexed existing names, but we have not added to the burden by making any new ones for species already described.

What synonymy has now come to may be judged by an example supplied me by my friend Mr. C. B. Clarke. For a single species of *Fimbristylis* he finds 135 published names under six

1 M. Alph[illegible] ([illegible]) [illegible] but in a letter published in the *Bull. de* [illegible] *France* ([illegible]) "the real merit of Linnæus has been to combine for all plants the generic name with the specific epithet. It is im[illegible] the 'name' of a species consists, [illegible] in the combination, not in the specific epithet, [illegible] a mere fragment of the name, and meaningless when taken by itself."

1 Darwin, who always seems to me, almost instinctively, to take the right view in matters relating to natural history, is ("Life," vol. i. p. 364) dead against the new "practice of naturalists appending for perpetuity the name of the *first* describer to species. He is equally against the priority craze:—"I cannot yet bring myself to reject very *well-known* names" (*ibid.*, p. 369).

genera. If we go on in this way we shall have to invent a new Linnæus, wipe out the past, and begin all over again.

Although I have brought the matter before the Section it is not one in which this, or indeed any collective assembly of botanists, can do very much. While I hope I shall carry your assent with the general principles I have laid down, it must be admitted that the technical details can only be appreciated by experienced specialists. All that can be hoped is a general agreement amongst the staffs of the principal institutions in different countries where systematic botany is worked at; the free-lances must be left to do as they like.

Publications.

I have dwelt at such length on certain aspects of my subject that perhaps, without great injustice, you may retort on me the complaint of one-sidedness But when I survey the larger field of botany in this country, the prospect seems to me so vast that I should despair even if I had my whole address at my disposal of doing it justice. I think that its extent is measured by the way in which the publications belonging to our subject are maintained. First of all we have access to the Royal Society, a privilege of which I hope we shall always continue to take advantage for communications which either treat of fundamental subjects, or at least are of general interest to biologists. Next to this we have our ancient Linnean Society, with a branch of its publications handsomely and efficiently devoted to systematic work. Then we have the *Annals of Botany*, which has now, I think, established its position, and which brings together the chief morphological and physiological work accomplished in the country. Lastly, we have the *Journal of Botany*, a less ambitious but useful periodical, which is mainly devoted to the labours of English botanists. I remember there was a time when I thought that this, at any rate, was an exhausted field. But it is not so: knowledge in its most limited aspects is inexhaustible if the labourer have the necessary insight. The discoveries of Mr. Arthur Bennett amongst the potamogetons of the Eastern Counties is a striking and brilliant instance.

Besides the publication of the *Annals* we owe to the Oxford Press a splendid series of the best foreign text-books issued in our own language. If the thought has sometimes occurred to one's mind that we were borrowers too freely from our indefatigable neighbours, I, at least, remember that the late Prof. Eichler paid us the compliment of saying that he preferred to read one of these monumental books in the English translation rather than in the original. I believe it is no secret that botany owes the aid that Oxford has rendered it in these and other matters in great measure to my old friend the Master of Pembroke College, than whom I believe science has no more devoted supporter.

Palæobotany.

I have said much of recent botany; I must not pass over that of past ages. Two notable workers in this field have passed away since our last meeting. Saporta was with us at Manchester, and we shall not readily forget his personal charm. If some of his work has about it a too imaginative character, the patience and entire sincerity with which he traced the origin of the existing forms of vegetation in Southern Europe to their ancestors in the not distant geological past will always deserve attentive study. But in the venerable, yet always useful, Williamson we lose a figure whose memory we shall long preserve. With rare instinct he accumulated a wealth of material illustrative of the vegetation of the Carboniferous epoch, which, I suppose, is unique in the world. And this was prepared for examination with incomparable patience either by his own hands or under his own eyes. He illustrated it with absolute fidelity. And if he did not in describing it always use language with which we could agree, nothing could ruffle either his imperturbable good nature or the noble simplicity of his character. Truth to tell, we were often in friendly warfare with him. But I rejoice to think that before his peaceful end came he had patiently reconsidered and abandoned all that we regarded as his heresies, but which were, in truth, only the old manner of looking at things. And I think that if anything could have contributed to make his departure happy, it was the conviction that the completion of his work and his scientific reputation would remain perfectly secure in the hands of Dr. Scott.

Vegetable Physiology.

Turning again to the present, the difficulty is to limit the choice of topics on which I would willingly dwell. In an address which I delivered at the Bath meeting in 1888, I ventured to point out the important part which the action of enzymes would be found to play in plant metabolism. My expectations have been more than realised by the admirable work of Prof. Green on the one hand, and of Mr. Horace Brown on the other. The wildest imagination could not have foreseen the developments which in the hands of animal physiologists would spring from the study of the fermentative changes produced by yeast and bacteria. These, it seems to me, bid fair to revolutionise our whole conceptions of disease. The reciprocal action of ferments, developed in so admirable a manner by Marshall Ward in the case of the ginger-beer plant, is destined, I am convinced, to an expansion scarcely less important.

But, perhaps, the most noteworthy feature in recent work is the disposition to reopen in every direction fundamental questions. And here, I think, we may take a useful lesson from the practice of the older Sections, and adopt the plan of entrusting the investigation of special problems to small committees, or to individuals who are willing to undertake the labour of reporting upon special questions which they have made peculiarly their own. These reports would be printed *in extenso*, and are capable of rendering invaluable service by making accessible acquired knowledge which could not be got at in any other way.

We owe to Mr. Blackman a masterly demonstration of the fact, long believed, but never, perhaps, properly proved, that the surface of plants is ordinarily impermeable to gases. Mr. Dixon has brought forward some new views about water-movement in plants, which I confess I found less instructive than many of my brother botanists. They are expressed in language of extreme technicality; but, as far as I understand them, they amount to this. The water moving in the plant is contained in capillary channels; as it evaporates at the surface of the leaves a tensile strain is set up, as long as the columns are not broken, to restore the original level. I can understand that in this way the "transpiration current" may be maintained. But what I want to know is how this explains the phenomena in the sugar maple, a single tree of which will yield, I believe, 20–30 gallons of fluid before a single leaf is expanded.

We owe to Messrs. Darwin and Acton the supply of a "Manual of Practical Vegetable Physiology," the want of which has long been keenly felt. Like the father of one of the authors, "I love to exalt plants" (i. 98). I have long been satisfied that the facts of vegetable physiology are capable of being widely taught, and are not less significant and infinitely more convenient than most of those which can be easily demonstrated on the animal side. How little any accurate knowledge of the subject has extended was conspicuously demonstrated in a recent discussion at the Royal Society, when two of our foremost chemists roundly denied the existence of a function of respiration in plants, because it was unknown to Liebig!

Assimilation.

The greatest and most fundamental problem of all is that of assimilation. The very existence of life upon the earth ultimately depends upon it. The veil is slowly, but I think surely, being lifted from its secrets. We now know that starch, if its first visible product, is not its first result. We are pretty well agreed that this is what I have called a "proto-carbohydrate." How is the synthesis of this effected? Mr. Acton, whose untimely end we cannot but deeply deplore, made some remarkable researches, which were communicated to the Royal Society in 1889, on the extent to which plants could take advantage of organic compounds made, so to speak, ready to their hand. Loew, in a remarkable paper, which will perhaps attract less attention than it deserves from being published in Japan (*Bull. College of Agric. Imp. Univ. Tokio*, vol. i.), has from the study of the nutrition of bacteria, arrived at some general conclusions in the same direction. Bokorny appears recently to have similarly experimented on algæ. Neither writer, however, seems to have been acquainted with Acton's work. The general conclusion which I draw from Loew is to strengthen the belief that form-aldehyde is actually one of the first steps of organic synthesis, as long ago suggested by Adolph Baeyer. Plants, then, will avail themselves of ready-made organic compounds which will yield them this body. That a sugar can be constructed from it has long been known, and Bokorny has shown that this can be utilised by plants in the production of starch.

The precise mode of the formation of form-aldehyde in the process of assimilation is a matter of dispute. But it is quite clear that either the carbon dioxide or the water, which are the materials from which it is formed, must suffer dissociation. And this requires a supply of energy to accomplish it. Warington has drawn attention to the striking fact that in the case of the nitrifying bacterium, assimilation may go on without the intervention of chlorophyll, the energy being supplied by the oxidation of ammonia. This brings us down to the fact, which has long been suspected, that protoplasm is at the bottom of the whole business, and that chlorophyll only plays some subsidiary and indirect part, perhaps, as Adolph Baeyer long ago suggested, of temporarily fixing carbon oxide like hæmoglobin, and so facilitating the dissociation.

Chlorophyll itself is still the subject of the careful study by Dr. Schunck, originally commenced by him some years ago at Kew. This will, I hope, give us eventually an accurate insight into the chemical constitution of this important substance.

The steps in plant metabolism which follow the synthesis of the proto-carbohydrate are still obscure. Brown and Morris have arrived at the unexpected conclusion that "cane-sugar is the first sugar to be synthesised by the assimilatory processes." I made some remarks upon this at the time (*Journ. Chem. Soc.*, 1893, 673), which I may be permitted to reproduce here.

"The point of view arrived at by botanists was briefly stated by Sachs in the case of the sugar-beet, starch in the leaf, glucose in the petiole, cane-sugar in the root. The facts in the sugar-cane seem to be strictly comparable (*Kew Bulletin*, 1891, 35-41). Cane sugar the botanist looks on, therefore, as a 'reserve material.' We may call 'glucose' the sugar 'currency' of the plant, cane-sugar its 'banking reserve.'

"The immediate result of the diastatic transformation of starch is not glucose, but maltose. But Mr. Horace Brown has shown in his remarkable experiments on feeding barley embryos that, while they can readily convert maltose into cane-sugar, they altogether fail to do this with glucose. We may conclude, therefore, that glucose is, from the point of view of vegetable nutrition, a somewhat inert body. On the other hand, evidence is apparently wanting that maltose plays the part in vegetable metabolism that might be expected of it. Its conversion into glucose may be perhaps accounted for by the constant presence in plant tissues of vegetable acids. But, so far, the change would seem to be positively disadvantageous. Perhaps glucose, in the botanical sense, will prove to have a not very exact chemical connotation.

"That the connection between cane-sugar and starch is intimate is a conclusion to which both the chemical and the botanical evidence seems to point. And on botanical grounds this would seem to be equally true of its connection with cellulose.

"It must be confessed that the conclusion that 'cane-sugar' is the first sugar to be synthesised by the assimilatory processes seems hard to reconcile with its probable high chemical complexity, and with the fact that, botanically, it seems to stand at the end and not at the beginning of the series of metabolic change."

PROTOPLASMIC CHEMISTRY.

The synthesis of proteids is the problem which is second only in importance to that of carbohydrates. Loew's views of this deserve attentive study. Asparagin, as has long been suspected, plays an important part. It has, he says, two sources in the plant. "It may either be formed directly from glucose, ammonia (or nitrates) and sulphates, or it may be a transitory product between proteid decomposition and reconstruction from the [illegible] (*loc. cit.*, 64).

In some remarks I made to the Chemical Society I ventured to [illegible] suggestion that the chemical processes which took place under the influence of protoplasm were probably of a different [illegible] from those with which the chemist is ordinarily [illegible]. The plant produces a profusion of substances, [illegible] great facility, which the chemist can only build [illegible] way. As Victor Meyer (*Pharm. Journ.*, 18[illegible]) [illegible] "In order to isolate an organic substance we [illegible] the purely accidental properties of [illegible]. In other words, the chemist only [illegible] stability; while it can not [illegible] which plays a part in the processes of life [illegible] every respect. I am convinced that if the [illegible] field of protoplasmic activity he will [illegible] limitations, and be prepared to [illegible] algebra, there may be more than one chemistry. I am glad to see that a somewhat similar idea has been suggested by other fields of inquiry. Prof. Meldola (NATURE, xlii. 250) thinks that the investigation of photochemical processes "may lead to the recognition of a new order of chemical attraction, or of the old chemical attraction in a different degree." I am delighted to see that the ideas which were floating, I confess, in a very nebulous form in my brain are being clothed with greater precision by Loew.

In the paper which I have already quoted, he says of proteids (*loc. cit.*, 13): "They are *exceedingly labile compounds* that can be easily converted into relatively stable ones. A great lability is the indispensable and necessary foundation for the production of the various actions of the living protoplasm, for the mode of motions that move the life-machinery. There is a *source of motion* in the labile position of atoms in molecules, a source that has hitherto not been taken into consideration either by chemists or by physicists."

But I must say no more. The problems to which I might invite attention on an occasion like this are endless. I have not even attempted to do justice to the work that has been accomplished amongst ourselves, full of interest and novelty as it is. But I will venture to say this, that if capacity and earnestness afford an augury of success, the prospects of the future of our Section possess every element of promise.

PHYSICS AT THE BRITISH ASSOCIATION.

THE proceedings of this Section were commenced by the delivery of the presidential address by Prof. W. M. Hicks. In seconding the vote of thanks to the President, Prof. Fitzgerald referred to the possible change of mass with temperature, suggested in the address, and pointed out that such a phenomenon would show itself by a deviation of planetary motions from strict conformity to Kepler's laws, owing to their change of mass on cooling.

Sir Douglas Galton exhibited plans of the German Reichsanstalt, and of the new buildings in course of construction, and gave a more detailed account of the management of this institution than is contained in his presidential address to the Association. His object in reading the paper was to revive a movement set on foot at a previous meeting by Prof. Oliver Lodge. The Committee appointed at that time to consider the question of a National Physical Laboratory for the United Kingdom made but little progress, possibly because they did not propose to develop any existing institution. He suggested that the scope of the Kew Observatory should be extended so as to include research, and that it be made the starting-point for the national laboratory.

A discussion followed, in which several members took part. Prof. Rücker lamented the want of concentration and organisation in research work, and thought a national laboratory might remedy this. He regretted that the day was passing away when a man could undertake both teaching and research, because, in his opinion, teachers should not give up research. Prof. Oliver Lodge drew attention to the enormous advantages possessed by a national institution, for carrying on researches extending over a long period. In a university laboratory such research would possibly be discontinued with a change of professor. The universities would still do pioneer work, discovering new fields of research and obtaining preliminary results. Prof. Fitzgerald, on the other hand, did not think it advisable to hand over research to a national laboratory, whereas he strongly advocated an extension of the standardising work performed at Kew. He believed that the highest kind of instruction was training in research work, and it was the function of the universities to give this instruction. Instead of that, the professors are called upon to cram old knowledge into immature and stupid students. The Section has appointed a Committee to reconsider the question of a national laboratory.

Prof. Henrici read a paper on the teaching of geometrical drawing in schools, which was, he said, as a rule very bad. He pointed out that Euclid's constructions are generally followed, the use of the set square being discarded and only straight-edges and compasses used. He urged the desirability of discarding Euclid in the teaching of geometrical drawing, advocating the use of the set-square from the very commencement. The examples ought to be so arranged that a student can verify his constructions for himself; he therefore suggested the appointment of a Committee to report on the whole question and issue

a syllabus of examples. This suggestion was adopted by the Section.

The range of subjects included in the work of the Section was perhaps nowhere better exemplified than in the passage to the next paper, a report on cosmic dust, by Dr. J. Murray. An examination of the red clay from the bottom of the Pacific Ocean, in places 1000 miles from any coast, enables three classes of magnetic particles to be distinguished; these are—crystalline fragments of magnetic or titanic iron, dark shiny spherules containing metallic iron, and the brownish spherules known as chondres. The various layers of manganese nodules found surrounding nuclei of tertiary teeth or bones contain these black and brown spherules, and there is every indication that the brown ones are of extra-terrestrial origin. In this case they ought to occur at all, or at any rate many, points on the earth's surface; Dr. Murray has, however, looked for them in vain both in the dust of Greenland glaciers and on the summit of Ben Nevis. He is of opinion that the accumulation of meteoric dust takes place with exceeding slowness, say about 20 lbs. of dust per square mile per century, and that the bed of the Pacific Ocean has not received one foot of deposit since the tertiary period. Consequently any attempt to gather these particles will probably be fruitless, unless continued over a long period. He wished for suggestions as to the best method of procedure in the future. It was pointed out that a good opportunity for the collection of meteorites will be afforded by the meteor shower of November 1899.

The Committee on underground temperature have been fortunate this year in obtaining records from a bore-hole in New South Wales, the first observations made in the southern hemisphere. The bore-hole is situated near Port Jackson, close to Sydney Harbour; it is 2929 feet deep, and contains water. The gradient observed was a small one, being a rise of 1° F. in descending 80 feet vertically. The observers suspected that the temperature of the rock was influenced by the proximity of the water in the harbour, but an examination of the temperature distribution in the harbour did not confirm this. Lord Kelvin suggested the African mines as a new field for observations.

Prof. S. P. Thompson reported the recommendations of the Committee on the size of pages of scientific periodicals. It is considered advisable to retain quarto and octavo sizes, and certain limits for text and margin are given for each of these sizes. There appeared to be a strong feeling against any change in the sizes of the Royal Society's publications. During the year the Committee will endeavour to induce other scientific societies to adopt the standard sizes recommended.

Prof. Rucker communicated the results of a comparison of magnetic standard instruments, made by himself and Mr. W. Watson. In his presidential address to the Section last year he showed that it was useless to proceed further with a magnetic survey until a direct comparison of standards used in the various observatories had been made, because it was well known that instruments differed greatly. During the year he has visited the various magnetic observatories, carrying a portable declinometer of the Kew pattern, and with Mr. Watson's assistance has directly compared the simultaneous readings of his declinometer and that of the observatory. Errors are found in the latter, which are in every case traceable to magnetic material in or on the wooden box containing the suspended magnet. If this box be replaced by an ebonite one, the error disappears. It is, however, easier to allow for the error than to get rid of it; its amount is perfectly definite.

On Friday the Section sat jointly with Section B. Lord Rayleigh read a paper on the refractivity and viscosity of these gases. He described how, by means of an electric arc, kept up for several weeks in a mixture of oxygen and atmospheric nitrogen, he finally obtained more than a litre of argon at atmospheric pressure. This proved to have the same density as the specimen obtained by the magnesium method. The refractive index was measured by the interference method of Fizeau, the two beams being separated by slits in front of the lens nearest the eyepiece. The latter was constructed of cylindrical lenses. To avoid the use of cross-wires, the tubes containing the gases under comparison were arranged so as not to occupy the whole field of view, some light passing parallel to, and outside them; two sets of fringes were thus obtained, which could be brought to coincidence by varying the pressure of either gas. Adjustments were made for several pressures, one of the tubes always containing air. The values of the refractivity ($\mu - 1$) were, for argon 0·961, and for helium 0·146, that of air being taken as unity. The viscosity of each gas was measured by its rate of flow through a capillary tube, the results being (air = 1) argon 1·21, helium 0·96. Lord Rayleigh mentioned that a sample of nitrogen collected from a Bath spring, where it bubbles out along with the water, gave the D_3 line of helium. Dr. Gladstone showed that the results of these experiments assign to argon the atomic weight 20, its specific refractive energy being intermediate between those of fluorine and sodium, but not between those of potassium and calcium.

Prof. Schuster then opened a discussion on the evidence to be gathered as to the simple or compound character of a gas from the constitution of its spectrum. Recent spectroscopic work in connection with argon and cleveite gas has directed attention to the double spectra exhibited by these substances, and conjectures have been made that the two spectra indicate the gases to be mixtures. Prof. Schuster expressed strongly the view that gases with double spectra are not necessarily mixtures or compounds. He quoted in support of this the cases of sodium and mercury vapours, and oxygen, in all of which the absorption spectrum differs from that of the luminous vapour. The difficulty is not explained by assuming dissociation to occur, because some substances have three or more spectra. He thought mere examination of spectra would not suffice to determine whether an unknown substance is an element, mixture of elements, or compound.

The despondent view of Prof. Schuster was not shared by Prof. Runge, of Hanover, who at this point contributed an account of the researches of himself and Prof. Paschen on the spectrum of cleveite gas, showing that it is a mixture. (An account of this work by the authors themselves will be found on p. 520.)

Dr. G. J. Stoney contributed to the discussion by a paper on the interpretation of spectra.

On Saturday the Section was subdivided into two departments, mathematics and meteorology.

In the department of mathematics, Lord Kelvin read a paper on the translational and vibrational energies of vibrators after impacts on fixed walls, in which he sought to find an exception to the Maxwell-Boltzmann theorem relating to the average translational energy of the molecules of a gas. He calculated the time-average of the translational energy of a free particle after coming into contact with a vibrating particle, and found it always in excess of that which would be given by the Maxwell-Boltzmann law, though approximating more nearly to that average when the number of encounters was considerable; and that it seemed ultimately to give a total average out of accordance with the law. In the discussion which followed, Mr. G. H. Bryan pointed out that the Maxwell-Boltzmann law referred to the statistical average energy of a great number of particles, not to the time-average energy of a single particle.

Prof. Hicks, in his paper on a spherical vortex, stated that he had proved the possibility of building up a compound spherical vortex consisting of successive shells in which the rotation is oppositely directed, the vorticity and size of each shell satisfying a definite relation. In a paper on bicyclic vortex aggregates, he stated that it was possible, with given current and vortex-sheets, to have a steady *spiral* motion round an axis, compounded of motion in planes through the axis and motion in circles round the axis, the cyclic constants of the two component motions being independent of each other.

Mr. G. T. Walker showed an ingenious top in the shape of a flattened ellipsoid in which rotation could become converted into oscillations, and *vice versa*, by means of an adjustable piece which could be arranged unsymmetrically.

Dr. Burton made some suggestions as to matter and gravitation in the cellular vortex ether described in Prof. Hicks's presidential address.

Mr. P. H. Cowell read an important paper on recent developments of the lunar theory, chiefly by Dr. G. W. Hill, extended in the current number of the *American Journal* by an admirable paper by Prof. E. W. Brown. The order of work in attacking problems in the lunar theory is quite altered and much simplified in the new method. In a short discussion which followed, Mr. Cowell stated that Prof. Brown was engaged in bringing out a treatise on the lunar theory.

Prof. J. D. Everett read a paper on absolute and relative motion; and Mr. W. H. Everett made a communication on the calculation of the magnetic field due to a current in a solenoid.

In pure mathematics, Major MacMahon gave an interesting method of graphically representing partitions of numbers.

Colonel Cunningham read a paper on Mersenne's numbers, which are numbers of the form $2^q - 1$, where q is a prime, and which were first discussed by Mersenne about the year 1664. Colonel Cunningham also described a book of tables which he proposed to calculate, giving the solution of the congruence $2^x \equiv R$ (mod. p) for all moduli (p) which are primes, or powers of primes, up to 1000. There are to be two tables for each modulus, one giving the values of R for a series of values of x; and the other giving the smallest values of x for a series of values of R. He described some of the uses of such a table, and stated that the plan on which it would be drawn up would be precisely like a somewhat similar table by Jacobi, described in Prof. Cayley's report on mathematical tables in the British Association Report of 1876.

Prof. Alfred Lodge drew the attention of the Section to a multiplication table up to 1000 × 1000, drawn up by Mr. M. B. Cotsworth, of Holdgate, York, which was exhibited; it is similar to Crelle's table of the same extent, though in some respects more convenient.

Prof. M. J. M. Hill described two species of tetrahedron, the volume of any member of which can be determined without using the proposition that tetrahedrons on equal bases, and having equal altitudes, are equal.

In the department of meteorology, Mr. Eric S. Bruce put forward a new theory of lightning flashes, based on the principle of the pin-hole camera. The light from a concealed flash might, he supposed, pass through a small aperture in the concealing cloud and fall on another cloud, forming an inverted image of the flash. If there were several apertures we should have as many images. They would be faint, possibly too faint to affect a photographic plate. Moreover, if the receiving cloud were of irregular shape, an originally straight flash would appear distorted into a zig-zag line on the cloud. Mr. Symons thought a brighter patch of light ought to occur at the angles of the image thus distorted, and he scarcely thought the conditions imagined by Mr. Bruce corresponded with those of nature.

The report of the Committee on earth tremors was presented by Mr. Symons, who, in referring to the delicacy of the instruments used in their observations, said that an angle equal to that subtended by a chord 1 inch long at the centre of a circle 1000 miles in radius could be detected. Since last report two similar pendulums have been purchased, of the kind described in NATURE, vol. l. pp. 246-249 (1894); each possesses its own photographic recording apparatus. One of these has been recently erected in the cellar of Mr. Davison's house in Birmingham; the other should have been placed in a house three-quarters of a mile to the east, but this was found impracticable. It will be placed somewhere in the neighbourhood, and comparisons of the records of the instruments will be made during the year, after which the second one will be available for another station. An appendix to the report by Mr. Davison gives the bibliography and classification of horizontal pendulums.

Prof. John Milne gave an account of the long report of the Committee on seismological phenomena in Japan. This commences by a reference to the great loss caused by the recent fire at Prof. Milne's house and observatory, after which follows a description of the records of the Gray-Milne seismograph. Attached to the report is a catalogue of 8331 earthquake shocks recorded in Japan between 1885 and 1892, giving full particulars of the centre and area of disturbance. It enables the approximate *weight* of each to be found, and permits the division of Japan into fifteen distinct seismic districts. The next section of the report deals with the rate of propagation of earthquake disturbances from Japan to Europe. The small tremors which occur in the ten seconds or so before an earthquake shock are transmitted to Europe, but they are spread over half an hour; it appears, therefore, that the preliminary tremors either travel more quickly, or reach Europe by a shorter route than the main shock. The latter is known to travel along the surface at about 3000 metres per second. Do the tremors travel at 8000 to 11,000 metres per second, or do they pass through the earth, along a chord? If the latter, we may hope for some further knowledge concerning the interior of the globe. Prof. Milne has set up horizontal pendulums in nearly a score of places, and finds great differences in their behaviour. They all exhibit a general displacement, *i.e.* tilt, in the same direction, and similar long period movements. Examined from hour to hour, however, none of them show the existence of a diurnal wave. After a long and very laborious search, graphically described to the Section by Prof. Milne, he succeeded in tracing this diurnal effect to the local removal of load from the alluvium by greater evaporation from exposed areas. At night the movement is slight, and is probably accounted for by the condensation, at the cold surface, of aqueous vapour after rising through the warm earth. Some observations have been made on the disturbance of the pendulums by earth tremors. Their cause has not been ascertained, but they always occur with greatest intensity between 5 and 9 a.m. They are most marked with a steep barometer gradient and consequent wind, local or distant.

As Prof. Milne has now returned from Japan, and the earthquake catalogue is completed, the Committees on earth tremors and seismological phenomena have united under the latter name. The new Committee is a large one, and with Prof. Milne and Mr. Davison as joint secretaries, it ought to do good work.

A new theory of thunderstorms was advanced by Prof. Michie Smith in his paper on Indian thunderstorms. His observations, made at Madras, showed that sheet-lightning occurs there every evening during several months of the year, always in the south-west and near the horizon. Lightning phenomena in the morning occur, on the other hand, in the north-east. The phenomena consist of actual discharges between two clouds, or two portions of the same cloud, and are not reflections of distant lightning; they take place in the upper portions of low-lying cumulus clouds. Prof. Smith attributes them to the clouds formed in the regions of still air at the meeting of the land and sea breezes, and has observed in these regions the simultaneous rise of two close parallel clouds from the edge of the cumulus; such clouds are scarcely distinguishable except with oblique illumination, and it is within, or between, them that the discharges occur. The time of their formation depends on the hour at which the sea breeze sets in, being roughly three hours later. The land breeze being dry and dusty is negatively charged, while the sea breeze is known to carry a strong positive charge: equalisation of the electrical states of the clouds formed out of these will, therefore, give rise to lightning. Prof. Smith referred to the iridescence or nacreous appearance of the edges of the clouds when rapidly sinking, and considered this effect to be due to the dust left behind by them.

This paper gave rise to an interesting discussion, chiefly with reference to the origin of dust in clouds, and the source of their electricity. Mr. John Aitken pointed out that thunderstorms are most probably the effect, not the cause, of purifying the air. He gave instances of thunderstorms on several successive days, all of which left the air dusty and impure; eventually the air cleared, and no more thunder occurred. Prof. Schuster alluded to the fact that twenty-five theories of thunderstorms had been put forward in a dozen years, and in a single year five appeared. He attributed the positive charge of the sea breeze to the electrification of the air by the spray from the breaking waves; Lenard has shown that the spray of pure water gives a negative charge to the air, while that of salt water communicates a positive charge. He believed the dust of clouds to be acquired locally, except that at high altitudes, which we know to be carried long distances. A proof of this is to be found in the Himalayas where certain valleys are dusty and others fairly free from dust, although all receive the wind from the Indian plains. His observations of nacreous clouds in England had led him to connect them rather with the ice particles of cirrus clouds than with dust. To this latter point Prof. Michie Smith replied that the nacreous appearance fits the edge of the cumulus so closely that he believes the two to be connected.

The Committee on the application of photography to meteorology are proceeding with the photography of clouds near the sun by means of two cameras at a fixed distance apart, and exposed simultaneously by an electrical arrangement. In this way they hope to obtain absolute measurements of cloud altitudes. For purposes of measurement the sun's image appears in all the photographs. A photograph of the rainbow, by Mr. Andrews of Coventry, is the first of its kind received by the Committee. It shows the secondary bow, and the greater brightness of the region within the bow.

During a recent visit to the Engadine, Prof. Schuster has made observations on the atmospheric electricity near the ground at different heights above sea-level. The readings were taken with Lord Kelvin's portable electrometer, which worked very satisfactorily and seems well adapted for such purposes. In all cases positive charges were found, increasing with height but in an apparently erratic fashion. The normal positive charge at the foot of a glacier was found to be strengthened by a wind blowing down it, and Lenard's observations on the negative

electricity of waterfalls were all confirmed. The daily curve of atmospheric potential in the valley of Pontresina shows a maximum at 11 a.m., dipping a little and rising again to an afternoon maximum at 5 p.m., then rapidly descending as the evening breeze sets in. Discussion on the paper related chiefly to the behaviour and temperature errors of portable electrometers, the latter being somewhat large and quite unexplained. Prof. Ayrton suggested a crucial experiment to determine whether atmospheric electricity is due to an actual distribution in the air, or to induction from the earth's surface.

The report of the Ben Nevis Observatory for 1894 was presented. The mean hourly velocity of the wind at the top of the mountain, and the mean rainband, are included in the report for the first time. Dr. Buchan and Mr. Omond have made progress in collating the simultaneous records made at Fort William and the summit; the differences between them are to be examined especially with respect to their bearing on coming storms. Even at this stage the results indicate that the present theory of cyclones requires great modification.

The first part of Monday's sitting was devoted to a discussion on the nature of combination tones. Prof. Rücker gave an admirable account of the history of the subject, pointing out that Helmholtz originated both the theory that they are objective, and that which supposes them subjective. He reviewed the theories of Prior and others, according to which summation and difference tones are explained as beat tones of various kinds: and he called attention to Helmholtz's proof that an asymmetrical elastic body, such as the disc of a microphone or the drumskin of the ear, would resound to the difference tone between two notes. Prof. S. P. Thompson regretted that in his historical survey Prof. Rücker did not refer to his own work. He read communications from König and Hermann, defining their views. König distinguishes between beat tones, which can be resonated, and difference tones, to which the resonator does not respond; the latter are subjective. Hermann objects to Helmholtz's theory that it is inadequate to account for the loudness of the combinational tones. Prof. Thompson mentioned experiments to show that difference tones may be obtained by sending one sound to each ear, and in other cases where the drumskin does not receive the sounds. He described also the effect of periodically intermitting a single tone, or of suddenly and periodically changing its phase, in both of which cases a tone is heard the pitch of which is the frequency of phase-change or intermittence.

Prof. Everett sought for the cause of combination tones in the air itself, which would be disturbed unsymmetrically by two sounds of finite amplitude. He thought, however, that in the combined effect of two tones, the vibration corresponding to the fundamental Fourier term common to each would be louder than the difference tone, a view in which Lord Kelvin concurred. Dr. Burton pointed out that Prof. Everett's explanation of combination tones would apply also to phase tones and intermittence tones. Dr. G. J. Stoney thought resonance by the mouth-cavity was an important factor in hearing, and in the selection of separate sounds from among a number. There was a general agreement that summation tones have never been heard, and probably do not exist.

Mr. E. H. Griffiths opened a discussion on the desirability of a new Practical Heat Standard. He showed that the use of water as the standard substance in heat measurements had led to great confusion, on account of the various assumptions as to its variation of heat-capacity with temperature. The curves of heat-capacity of water and temperature, used by different experimenters, were exhibited; according to which the author's results furnished a value about the mean of those of recent observers. Mr. Griffiths suggests as a heat unit, absolute, independent of any one person's results, and convenient in magnitude, the heat energy of 42 million ergs. To interpret it as a water standard he proposes to take it as the thermal capacity of a gramme of water at 10° C., as measured by the hydrogen thermometer; and he gives a formula to find the heat-capacity at other temperatures than 10° C. Lord Kelvin said that Prof. Rankine had previously suggested the dynamical specific heat of water as a standard. Mr. W. N. Shaw thought it advisable to make a distinction between the numbers for the absolute thermal capacity and the specific heat of a substance. He believed this would be done most simply by taking the thermal unit as the heat energy of a million ergs; the specific heat of water at 10 C. would then be unity, and its thermal capacity 42 units. The choice of a thermal unit has been referred to the Electrical Standards Committee.

Dr. C. H. Lees gave an account of the method and results of experiments on the thermal conductivity of mixtures of liquids. The method used was that of Christiansen, in which the heat is conducted through the liquid enclosed between two copper discs, and confined by an ebonite ring if necessary. The results show that the conductivity of mixtures of two liquids is less than the value calculated by the ordinary law of mixture, at any rate for water, ethyl alcohol, methyl alcohol and glycerine. Dr. Lees undertook the experiments to verify certain relations suggested by Prof. H. F. Weber between molecular weight, density, specific heat and thermal conductivity.

A paper by Prof. Ramsay and Miss Dorothy Marshall was read by the latter, the subject being a method of comparing heats of evaporation of liquids at their boiling-points. After remarking that the data of heats of evaporation are very scanty and discrepant, Miss Marshall described a method by which two liquids, kept at their boiling points by jackets of their vapour surrounding them, are boiled by means of equal bare platinum wires heated by an electric current. A comparison of the amounts of the liquids evaporated in a given time gives the ratio of heats of evaporation. For absolute values a special determination was made on benzene by Mr. Griffiths and Miss Marshall. Alcohol was carefully compared with benzene, and all other liquids were then compared with alcohol. Water was very erratic in its behaviour, probably because of its greater electric conductivity.

Mr. G. U. Yule exhibited a harmonic analyser.

At the meeting on Tuesday, Lord Kelvin described the results of experiments for the electrification and diselectrification of air and other gases, made by Messrs. Maclean and Galt, and himself. In the earlier experiments the air inside a metal can was electrified by points, the can being put to earth: on insulating the can and blowing out the air, the charge acquired by the can was equal and opposite to that of the air. Electrification of air and other gases in gas-holders over water, by points and flames, was also tried, greater electric densities being thus obtained than by the previous method. The maximum effects were $1\cdot5 \times 10^{-4}$ electrostatic units per c.c. for air, and $2\cdot2 \times 10^{-4}$ for CO_2. The gases were diselectrified by "filtering" them through metal tubes containing conducting wire gauze and cotton wool. Very little electrifying effect was found when uncharged air passed through a platinum tube 100 cm. long and 1 mm. diameter, until the tube was made red-hot, in which case the air acquired a strong positive charge. Prof. Oliver Lodge suggested the use of a filter consisting of a metal tube, highly polished inside and illuminated by an electric beam shining into its interior. Lord Kelvin said that in all Hertz's or Elster and Geitel's experiments on diselectrification by light, the charge of the air round the illuminated body should be examined.

Prof. Rücker made a communication on vertical (earth-air) electric currents. At the meeting of the Association last year, Dr. Adolph Schmidt accounted for a portion of the earth's magnetism by assuming electric currrents to pass vertically between earth and air. Such currents would be shown by the non-vanishing of the line-integral of magnetic force when taken round a closed circuit on the earth's surface. The matter was tested in this way by Messrs. Kay and Whalley, using four independent circuits, three in Great Britain and one in Ireland, and obtaining the data of magnetic force from the surveys of 1886 and 1891. The results do not decide the general question, but they show that in the United Kingdom the upward current has certainly not more than one-tenth of the value required in Dr. Schmidt's theory. Lord Kelvin calculated that the current assumed by Dr. Schmidt (0·1 ampere per square kilometre of surface) amounts to a removal of the fine-weather charge of the air near the earth 36 times per second. Dr. Rijchevorsel said he understood that magnetic observations were about to be made in Switzerland, which would furnish data for similar calculations there.

Mrs. Ayrton made a communication on the connection between potential difference, current and length of arc, in the electric arc. The results of carefully-performed experiments, verified also by recalculation from the data of other observers, show that the following relations hold:—(1) For constant length of arc the power (number of watts used in the arc) is a linear function of the current; (2) for constant currents the power is a linear function of the length of arc: (3) for constant length of arc the curve of potential difference and current is a rectangular hyperbola. All these laws are included in the President's statement that the surface with potential difference, current and arc length as coordinates, is a hyperbolic paraboloid.

Prof. Ayrton read a paper by Mr. Mather and himself, in which arguments were advanced against the existence of a back electromotive force in the electric arc. The authors describe a method of measuring the true resistance of the arc, namely the ratio of a small increase of potential difference to the corresponding increase in the current; this, of course, is a negative quantity. The same authors described a magnetic field tester, an application of the ordinary exploring coil and ballistic galvanometer method, with a spiral spring to effect rapid rotation of the exploring coil, and a modified D'Arsonval galvanometer with shuttle-wound coil capable of rotating through several turns without losing the proportionality of angular displacement and restoring force.

The velocity of light in vacuum tubes conveying an electric discharge formed the subject of a paper by Messrs. Edser and Starling. Vacuum tubes were placed in the path of the two beams of a Fizeau interference apparatus, and the position of the bands observed. No appreciable shift of the bands was obtained either by setting up an induction-coil discharge, or by the discharge of [illegible] through the tubes when placed in series with a piece of wet string. The discharge in the latter case lasted one-thirtieth of a second, and the authors show that a disturbance of the bands of so long duration would have been observed.

Mr. F. G. Baily read a paper on hysteresis of iron in an alternating magnetic field, in which he showed that the hysteresis of iron increases with the field up to a maximum value, in accordance with Ewing's theory. The experiments were made by the [illegible] method, using a small laminated armature consisting of thin discs of charcoal iron; the most intense magnetic field used was 22,000 C.G.S. units, and the hysteresis was measured by the rise of temperature of the armature.

On Wednesday, Dr. Gladstone and Mr. W. Hibbert made a communication on the change of molecular refraction in salts or acids dissolved in water. The molecular refraction of a substance [illegible] when the substance changes its state, and a further slight alteration takes place on diluting its solution; the authors have obtained some evidence of a close connection between these changes and the variations of electric conductivity [illegible] its solutions. Such a connection would have an important bearing on the theory of solution.

The report of the Electrical Standards Committee was read. The Committee [illegible] during the year to institute a comparison between the British and German standards of resistance, and have prepared coils for this purpose, which have already been tested at the Reichsanstalt. The Committee, recognising the need for practical units of magnetic field and magnetic potential, recommend the tentative adoption (1) of a unit equal to 10^8 C.G.S. lines, to be called a *weber*, (2) the C.G.S. unit of magnetic potential, to be called a *gauss*. They also recommend that the termination [illegible] be used in describing the properties of a piece of matter, e.g. the resistance of a copper wire, and the termination [illegible] for the specific properties of the material, *e.g.* [illegible] of copper would mean the resistance of a centimetre [illegible]. Prof. Oliver Lodge explained, and advocated [illegible] the proposed units. Prof. S. P. Thompson, while agreeing with the Committee as to the desirability of having [illegible] field and magnetic potential, thought the choice [illegible] should be left with the practical men who use them. He considered the proposed *weber* was too large, and advocated the retention of the C.G.S. "line," using the kilo- and [illegible] multiples; further, he did not see any necessity for [illegible] the ampere turn in order to replace it by the [illegible]. Prof. Thompson pointed out a more formidable objection, [illegible] the American Institute of Electrical Engineers have [illegible] *weber* to a different unit, and have suggested [illegible] for the gauss. Several members continued the [illegible] and Prof. Perry expressed his opinion that the [illegible] ought to be settled by a general congress.

[illegible] apparatus for tracing the form of the wave of [illegible] alternate current circuit were exhibited and described [illegible] Messrs. Barr, Burnie and Rodgers, the other [illegible] Mr. Mather.

[illegible] the apparatus designed for the [illegible] temperature thermometers at Kew Observatory [illegible] Callendar and Griffiths platinum [illegible] glass or porcelain tube, and can be [illegible] thermometer to be calibrated, in [illegible] sulphur vapour, according to the [illegible] measured by a Wheatstone [illegible] are enclosed in a copper box, five sides of which are immersed in a water-bath of constant temperature, while the top is surmounted by a case similar to that of a chemical balance. The coils of the bridge are of platinum-silver, wound double, and are not embedded in paraffin, the object being to allow them to assume the temperature of the box and surrounding water as quickly as possible.

A vote of thanks to the Chairman and Secretaries terminated the proceedings.

CHEMISTRY AT THE BRITISH ASSOCIATION.

With the exception of Prof. Runge's announcement of the undoubtedly compound nature of helium, few of the communications laid before Section B at Ipswich are likely to awaken great interest outside chemical circles. The discussions, however, which are now a recognised feature of these meetings, were especially successful, and it is not too much to hope that the joint meeting with the newly-formed Botanical Section may be the means, if only indirectly, of bringing about results of great importance to the agricultural community.

Following the President's valuable address, Sir Henry Roscoe and Dr. A. Harden communicated to the Section an interesting discovery in historical chemistry. It has been generally assumed that Dalton arrived at the idea of atoms with definite weights from a consideration of the proportions in which certain elements combined. From the examination of a number of manuscript volumes of Dalton's own laboratory notes, which they have recently discovered in the library of the Manchester Literary and Philosophical Society, Sir Henry Roscoe and Dr. Harden conclude that Dalton worked out his theory solely from physical considerations as to the constitution of gases. His mind being saturated with Newton's ideas concerning atoms, it was from these that his own atomic theory was developed.

Later on, quoting not only his own results but those of other chemists, he seems to have been led to the law of multiple proportions as the only conceivable mode of combination between atoms. Extracts were given from his notes showing that certain numbers, usually quoted as having led him to his atomic theory, *e.g.* the analyses of marsh gas and olefiant gas, were only inserted in his tables some time after the publication of his ideas.

Prof. Armstrong said it was satisfactory to learn that Dalton had really arrived at his conclusions from truly philosophical considerations, without reference to the very crude numbers, usually quoted as sufficient basis for the laws that he worked out.

The report of the Committee on the teaching of science in elementary schools was read by Dr. J. H. Gladstone. During past years there has been an increase in the number of subjects taught, and in the number of pupils receiving instruction. The alteration in the system of inspection will have an especially useful effect in the teaching of science. The question of the training of teachers is discussed in the report. A course for mistresses on domestic science, dealing as far as possible with the nature of the processes and materials employed in the household, has been found successful. The great obstacles to good science teaching at the present time in elementary schools are: (1) Large classes; (2) multitude of subjects; (3) insufficiency of the training course for teachers in science subjects; (4) effects of the old science and art system, which is clearly far too formal, and pays far too little attention to ordinary requirements.

The courses on elementary physics and chemistry, and the science of common things are found to be more attractive than pure chemistry.

Other subjects dealt with in the report are school visits to museums; the right method of giving object lessons; and the teaching of the metric system. Finally it is suggested as a question worth consideration, whether the recognised school age should not be raised from thirteen to fourteen.

In the discussion which followed the reading of the report, the relation of County Councils to elementary schools was debated, and it was contended that these are helped indirectly by the Councils providing facilities for the training of teachers.

Mr. G. J. Fowler read a paper on the action of nitric oxide on certain salts, by H. A. Auden and G. J. Fowler, in which the action of nitric oxide on different salts at various tempera-

tures is described. Oxy-salts have been chiefly examined, the most interesting results being obtained with the chlorates and iodates of potassium and silver. With potassium chlorate action takes place at the ordinary temperature, chlorine being evolved, but no potassium chlorate being formed. With silver chlorate, chlorine is also evolved, but some chloride is obtained. Potassium iodate yields iodine but no potassium iodide at a low temperature, while silver iodate is completely converted into iodide, no iodine being liberated, or silver nitrate formed. It is suggested that these results tend to show a difference in constitution between the silver and potassium salts.

Prof. Clowes gave an account of further experiments on the respirability of air, in which a candle flame has burnt till it is extinguished. He finds that an atmosphere, which contains oxygen 16·4 per cent., nitrogen 80·5 per cent., carbon dioxide 3·1 per cent., will extinguish a candle flame, but is still, according to the experiments of Haldane, not only respirable, but would be breathed by a healthy person for some time without injury. An atmosphere which extinguishes a coal-gas flame, however, appears to approach closely to the limits of respirability, as far as the proportion of oxygen which it contains is concerned. The candle and lamp flames should be discarded as tests of the respirability of air in favour of the coal-gas flame.

A paper was read by Mr. D. J. P. Berridge, on the action of light upon the soluble metallic iodides in presence of cellulose, in which it was shown that the amount of iodine liberated from potassium iodide by the combined action of light, air and moisture, is greatly increased by the presence of cellulose, this substance probably combining with the potassium hydrate liberated in the reaction. By investigating the conditions of formation of the chocolate stain obtained when note-paper containing starch, and soaked in potassium iodide solution, is exposed to light, evidence is obtained of the formation of a tri-iodide of potassium. The iodides of sodium, calcium, strontium, barium, iron, and zinc, all behave like the potassium salt; cadmium seems alone unable to form a higher iodide.

Dr. C. A. Kohn read the second report of the Committee on quantitative analysis by means of electrolysis. The bibliography of the subject has been completed. The experimental work has been carefully organised, and the results on the determination of bismuth and of tin are nearly complete.

Sir H. E. Roscoe presented the report of the Committee appointed to prepare a new series of wave-length tables of the spectra of the elements.

Some interesting communications were made to a joint sitting of Sections A and B; and the account of these, which we give in our report of the work of the former Section, is supplemented by the following notes on Dr. Gladstone's and Prof. Schuster's communications.

Dr. Gladstone's paper was on specific refraction and the periodic law, with special reference to argon and other elements. In former years he had shown that the specific refractive energies of the elements in general were, to a certain extent, a periodic function of their atomic weights. With regard to argon, the specific refractive energy of argon gas as reckoned by Lord Rayleigh's data is 0·159. At the suggestion of Deeley, the bearing of this result on the atomic weight of argon was considered. If the atomic weight be 19·94, the molecular refraction will be 3·15. This figure is almost identical with that belonging to oxygen and nitrogen gas, and differs considerably from that of calcium, which has a molecular refraction of 10·0 and a specific refractive energy of 0·248. These facts tend to suggest an atomic weight of 20 for argon, and to place it in the vicinity of the alkali metals.

The discussion, which was opened by Prof. Schuster, on the evidence to be gathered as to the simple or compound nature of a gas from the constitution of its spectrum, dealt with matters of rather more physical than chemical bearing. Of special interest to chemists, however, was the evidence cited by Prof. Schuster for considering that the variations noticed in the spectra of sodium, nitrogen, and mercury under different conditions were due to differences in atomic aggregation.

Monday's sitting was devoted to a discussion, held in conjunction with Section K (Botany), on the relation of agriculture to science. It was introduced by Prof. R. Warington in a paper entitled, "How shall agriculture best obtain the help of science?" This was devoted to a consideration of the best means for diffusing a knowledge of the scientific principles of agriculture. Certain things could be usefully done by a Board of Agriculture, and others by County Councils. The formation of a really complete agricultural and horticultural library, freely open to the public, and the maintenance of an English agricultural journal, are matters which might fall to the Board of Agriculture. The advantages to be derived from a Government laboratory and experimental station were dwelt upon. Local stations and secondary agricultural schools should be maintained by the County Councils, who also should inspect the technical instruction in their locality. The foundation of habits of observation and logical reasoning must be laid in the elementary school if higher instruction is afterwards to be given. Higher qualifications should be required for agricultural lecturers than is at present the case.

Mr. T. Hendrick contributed a second paper. He spoke of the apathy and even hostility to science shown by the practical agriculturist, and considered the reasons for this attitude.

In other countries national systems of agricultural education and research have been founded by the State. It is hopeless to look to local effort and support, because the practical man expects immediate results, and results out of all proportion to the time and money expended in obtaining them. The time has come when the State must take part in the work and devote to it much larger sums than at present.

Mr. Thiselton-Dyer said that the matter had been carefully considered by the last Government. It was difficult, however, to persuade the Treasury that agriculture was entitled to receive special aid of a kind not given to any of our other great industries, such as iron and textiles. Personally he looked to individual effort and munificence to supply what was needed.

Prof. Marshall Ward pointed out that it was of extreme importance that the results of any investigations should be made known at once and accurately to the practical man, and this was work which might very well be undertaken by Government, but he deprecated any direction or control from a Government department in any matters of original research.

Prof. J. R. Green pointed out the necessity for investigations on vegetable physiology, as bearing on the growth of crops.

Sir Douglas Galton agreed with Mr. Dyer that agriculturists must look to themselves for help, rather than to the Government. The obtaining of really good teachers was the great difficulty.

Lord Walsingham spoke of the difficulty in producing crops which would realise a profit. Wheat-growing was unprofitable in England, and his own attempts to grow tobacco were frustrated by the heavy duty.

Sir J. Evans and Sir H. Roscoe spoke of the work of the County Councils, and Prof. Perceval gave an account of the courses at Wye College.

Mr. J. Long considered that schools and colleges for boys and youths and demonstration plots for adult farmers were the best means of bringing home the benefits arising from the application of science to agriculture.

Mr. J. R. Dunstan, in a paper on the subject under discussion, contended that courses of lectures were necessary as pioneer work. Unless farmers have a general knowledge of the principles of science, they cannot really understand the results of experiments.

Prof. Liveing advised the co-operation of County Councils in maintaining a central experimental station. He described the system of agricultural teaching adopted at Cambridge.

Mr. Avery gave some account of the agricultural side attached to the Ashburton School in Devon, and spoke of the difficulty of obtaining pupils.

Mr. T. S. Dymond emphasised the necessity of a knowledge of scientific principles, if farmers were to properly understand experimental results.

Mr. C. H. Bothamley considered agricultural sides to secondary schools much better than schools restricted to farmers' sons. The value of demonstration plots, as distinguished from experimental plots, was very great.

Prof. Warington, in reply, remarked that the whole agricultural position was such that if anything was to be done, it must be done at once, they could not afford to wait.

Mr. T. B. Wood gave an account of work at the experimental plots in Suffolk and Norfolk. The experiments in Suffolk are conducted at two stations with soils typical of large areas in the neighbourhood, viz. at Higham, where the soil is thin and light with a chalk sub-soil, and at Lavenham, where it is a much deeper loam. The experiments at both stations consist in the growth of various crops in rotation with various manures. Each year a report of these experiments is printed and circulated,

during the summer, lectures and demonstrations are given on the plots. In Norfolk there are no definite fixed stations, but the use of land has been granted by farmers for experiments on the effect of manures on crops grown in the ordinary course of farming. Feeding experiments have also been conducted.

A paper from Prof. H. W. Vogel was read, in his absence, by the Secretary, dealing with the history of the development of orthochromatic photography. Photographs were shown illustrating the advantages of the use of eosin-silver as a sensitiser, the plates being more sensitive to the yellow rays than plates prepared with ordinary eosin.

Mr. C. H. Bothamley read a paper, illustrated by lantern slides and specimens, on the sensitising action of dyes on gelatino-bromide plates. The manner in which the dye acts was discussed, experimental evidence being given against Abney's view that an oxidation product, formed by the action of light on the dye, is the active agent in assisting the reduction of the silver bromide by the developer. The probabilities appear more in favour of Eder's view that the dye or sensitiser absorbs the energy of the light waves, and passes that energy on to the silver bromide with which it is associated, the silver bromide being thereby decomposed, and the so-called latent image being formed.

In reply to questions by Lord Rayleigh, Dr. Kohn, and Dr. Harden, Mr. Bothamley said that, so far as he was aware, photo-chemical action is always preceded by the absorption of light-waves, and in the case of colourless substances it is the ultra-violet rays that are absorbed and do the chemical work. Although the quantitative composition of the latent image is not known, we have, as a matter of fact, considerable knowledge as to its properties. There is no difficulty in determining the absorbing action and the sensitising effect on two contiguous strips of the same plate, and therefore under strictly comparable conditions. No relation can be traced between the fluorescence of a dye and its sensitising action.

The report of the Committee for investigating the action of light upon dyed colours was read by the President. With some few exceptions, all the available red, orange, and yellow colours, as applied to wool and silk, have now been exposed. (Tables are appended giving the general result of the exposure.) As before, it is found that many natural dye-stuffs are by no means so fast as is generally supposed, and are exceeded in this respect by artificial colouring matters.

Two papers on organic chemistry were contributed by Dr. J. J. Sudborough. In the first paper, the author describes the preparation of a monochloro-stilbene from deoxy-benzoin, differing from that described by Limin, as it is a solid, crystallising from alcohol in large colourless plates. An oily compound, corresponding to that of Limin, has been prepared, and is being further investigated. Other stilbene derivatives are described.

In a note on the constitution of camphoric acid, the author draws attention to the fact that, as regards its etherification, camphoric acid shows a marked resemblance to some of the polycarboxylic acids investigated by Victor Meyer and Sudborough, and to hemi-mellitic acid. The formulæ of Armstrong and of Bredt are regarded as best agreeing with the behaviour of camphoric acid in this respect.

Mr. H. J. H. Fenton gave an account of the preparation and properties of a new organic acid obtained by oxidising tartaric acid under certain conditions in presence of a ferrous salt. It can be obtained by the oxidation of moist ferrous tartrate in the air, and it is found that this reaction is much accelerated by light. The acid has been isolated, and proves to be a dibasic acid having the formula $C_4H_4O_6 + 2H_2O$. It gives a beautiful violet colour with ferric salts in presence of alkali. The constitution of the acid is under investigation. Heated with water it is resolved into carbon dioxide and glycollic aldehyde, the latter substance polymerising to form a sweet-tasting solid having the formula $C_6H_{12}O_6$.

The Committee for investigating isomeric naphthalene derivatives report that the fourteen isomeric tri-chlor derivatives have been obtained.

Dr. H. Wakemann read two papers on physical chemistry. In the first, experimental evidence was quoted, showing the validity of Van 't Hoff's constant, Dalton's law, &c., for very dilute solutions. In the second paper, on the velocity of reactions before perfect equilibrium takes place, an attempt was made to calculate constants of equilibrium from experiments made by others on the rate of acidification of phosphorus and other substances.

Messrs. C. F. Cross and C. Smith contributed a paper on the chemical history of the barley plant. The work had been carried out during the two years 1894 and 1895 on the experimental plots at Woburn, and the general conclusions drawn were that the conditions of soil nutrition had very little influence upon the composition of the plant; that the straw grown in wet seasons had a high feeding value and conversely a low paper-making value; and that the compounds known as furfuroids were continuously assimilated to permanent tissue in a normal season, but in a very dry season the permanent tissue is drawn upon by the growing plant for nutrient material which is ordinarily drawn from the cell contents.

THE RETIREMENT OF PROFESSORS.

THE report of the Committee appointed by the Treasury to consider the question of the desirability of a fixed age for the compulsory retirement of professors serving under the Crown has been recently published as a Parliamentary paper. The Committee consisted of Lord Playfair, Lord Welby, and Sir M. W. Ridley, M.P. Mr. C. L. Davies was secretary. The report, which is addressed to the Lords Commissioners of her Majesty's Treasury, is in the following terms:—

We have taken the evidence of presidents and professors of the Queen's Colleges in relation to their retirement upon superannuation at fixed ages, as determined by the Order in Council of August 15, 1890. We are of opinion that the Commission of 1888, upon the report of which, to some extent, that Order in Council was based, did not intend that the limitations of age applied to Civil servants generally should be deemed applicable to presidents and professors of colleges, who are appointed and serve under different conditions from those which prevail in the Civil Service.

These presidents and professors are appointed at a maturer age, and have, by the nature of their employment at seats of learning, less tendency than Civil servants to become inefficient at the age of sixty-five. Indeed, up to that age it is often found that their efficiency increases, by experience in teaching, as their age progresses, though undoubtedly a time does arrive when advancing age weakens the receptivity of the professor to new discoveries in science, and diminishes the inclination to alter his instruction in order to adapt it to these changes. When this occurs the students are the sufferers. In the German Universities this well-known degeneration of intellectual activity among the aged is partly compensated by the appointment of active young "extraordinary professors," who, though not on the ordinary staff of the colleges, are allowed to give competing lectures within their walls. In Edinburgh an extra-mural competition is encouraged, and in each Scotch University, when professors show diminished efficiency through age, it is the duty of the University court to superannuate the professor under a pension scheme, which is charged upon a fixed Parliamentary vote for all the Scotch Universities. The Queen's Colleges in Ireland are in a different position, for they are only to a small extent dependent upon votes in Parliament, being mainly supported out of the Consolidated Fund. They are, in consequence of this peculiarity, in more intimate connection with the executive Government, with which the presidents are in frequent communication as to the working of the college and the efficiency of the professors, who are appointed by the Crown and can be dismissed by the Crown. The statutes which govern the Colleges also emanate from the Crown, and are not, like those of other colleges, the product of academic autonomy.

Under these circumstances, we are of opinion that there should be fixed rules as to superannuation of presidents and professors, and that they should be made by college statutes and not by an Order in Council.

We are of opinion that when a professor reaches sixty-five years of age the president of the college should be bound to report to the Government the condition and efficiency of the teaching. If these are and continue to be satisfactory, the professor need not be superannuated till seventy, but at this age his retirement should be absolute.

In regard to presidents, we are of opinion that the age of seventy should be the period of retirement, but, should the visitors of the college formally report that the college would suffer by the loss of the experience which the president has acquired, we think that the Treasury, and not the Irish Office, should have power to continue him as president for a certain

number of years not exceeding five, so that at the age of seventy-five the retirement of a professor should be absolute.

We are quite aware that there are cases where professors at seventy and presidents at seventy-five are fully competent to discharge their duties, but the advantages derived from superannuation would be seriously diminished if, to meet these rare cases, there were uncertainty in regard to the application of a general rule. We have observed with regret that the *alumni* of the Queen's Colleges do not seek to go back to them as professors, and it was explained to us that one reason for this is that it is useless for them to prepare for a professorial career in these colleges while so much uncertainty prevails as to when the chairs will become vacant.

We also took the evidence of Profs. Lockyer and Rücker as to the conditions which prevail in the Government School of Science at South Kensington, and we found that the age of seventy for professors was considered a proper age for retirement under ordinary circumstances.

In our opinion, as the professors are not appointed till middle life, the addition of seven years to their period of service in calculating the amount of their superannuation obviously tends to secure eminent specialists as candidates for office. The power of voluntary retirement at the age of sixty has also much to commend it in this sense.

We have the honour to be
Your Lordships' obedient servants,
PLAYFAIR.
WELBY.
August 5, 1895. M. W. RIDLEY.

The report is followed by the minutes of evidence taken on June 17, 18, and 19, during which nine witnesses were examined.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

WE learn from *Science*, that Prof. Strahl, of Marburg, has been called to the chair of Anatomy in the University of Giessen, Prof. Hans Lenk, of Leipzig, to that of Geology in the University of Erlangen, and that Dr. Haecker, of Freiburg i.B., and Dr. v. Dalla-Torre, of the University of Innsbruck, have been made assistant Professors of Zoology.

PROF. CHAPMAN having resigned the professorship of Geology and Mineralogy in the University of Toronto, that chair is now vacant.

ACCORDING to *Science*, the conditions attached to the bequest made by the late Sir William Macleay to the Sydney University, to found a chair of Bacteriology, are such that the University has decided to decline the bequest. The money will therefore revert to the Linnean Society of New South Wales, to maintain a bacteriologist, who will carry on bacteriological investigations and also take pupils.

THE Examinations for the Royal Agricultural Society's Junior Scholarships have been fixed to take place on November 12 and 13 next, at the schools of candidates and at the Society's house, 13 Hanover Square. Ten scholarships of £20 each are thrown open for competition by candidates between the ages of fourteen and eighteen, and the subjects of examination comprise: (1) The Principles of Agriculture, especially with reference to the rotation of crops, the nutrition of plants and animals, and the mechanical cultivation of the soil; (2) Chemistry as applied to Agriculture; (3) Elementary Mechanics as applied to Agriculture; (4) Land Surveying. The latest date for receiving entries is October 15.

THE following courses of Gresham Science lectures are announced: "Physic," by Dr. Symes Thompson, on October 8 to 11; "Astronomy," by Rev. E. Ledger, on October 22 to 25; "Geometry," by Mr. W. H. Wagstaff, on November 19 to 22. The lectures will all be delivered at six o'clock in the theatre of Gresham College, E.C.

THE London Society for the Extension of University Teaching announces that, in co-operation with the Royal Geographical Society, arrangements have been made for the delivery at Gresham College of a course of twenty-five lectures by Mr. H. J. Mackinder, on "The Principles of Geography." The course is specially arranged for pupil teachers, and the Sessional Certificate, granted in connection therewith, will carry marks at the Queen's Scholarship Examination. The lectures will be given on Monday evenings at six o'clock, beginning October 7.

AT the City of London College, Moorfields, a course of twenty-five lectures on "The History of Chemical Discovery" will be delivered, under the auspices of the London Society for the Extension of University Teaching, by Prof. W. Ramsay, F.R.S. The course will be begun on Tuesday evening, October 8, at eight o'clock, and be continued weekly.

ON Tuesday evening, October 1, Sir Henry E. Roscoe will preside at a meeting at the Royal Victoria Hall, Waterloo Bridge Road, when the presentation of certificates to students of the Morley Memorial College will take place. The lecture arrangements at the Royal Victoria Hall for the month of October are as follow: On the 8th, Mr. W. P. Bloxam will lecture on "Combustion"; on the 15th, Dr. W. D. Halliburton will lecture on the "Human Brain"; and on the 22nd, Mr. P. J. Hartog will lecture on "Lavoisier."

SCIENTIFIC SERIALS.

American Journal of Science, September.—Distribution and secular variation of terrestrial magnetism, by L. A. Bauer. Starting from the supposition that the earth is magnetised symmetrically to its axis of rotation, the author shows that the chief cause of distortion of this primary field can be represented as due to a secondary polarisation approximately equatorial in direction. Of these two systems, the polar systems would have to be five or six times stronger than the equatorial. Since, in going round the earth along a geographical parallel of latitude, the deflections due to the secondary system almost balance each other, the inference might be drawn that the secondary field is in some way connected with the earth's rotation.—Relations of the diurnal rise and fall of the wind in the United States, by Frank Waldo. For January the rise of wind towards the mid-day maximum is followed by a more rapid fall over nearly the whole of the United States. For July the same law holds, except in the Western States, where the morning rise is more rapid. As regards the time during which the wind rises, this is about seven hours in the Mississippi valley. On the Atlantic coast there is a decrease from ten hours in the north to five hours on the coast of Florida.—The rate of increase varies from 0·4 to 0·6 miles per hour.—Native sulphur in Michigan, by W. H. Sherzer. During the past year interesting deposits of sulphur have been discovered in the Upper Helderberg limestone, of Monroe County, Michigan. The sulphur bed lies from sixteen to eighteen feet below the surface between a compact, dolomitic limestone and a calcareous sand rock. The sulphur generally occurs in bright lustrous masses towards the centre of the cavity, intermatted frequently with the above minerals. Fragments as large as a fist are readily removed. Some of the smaller cavities contain nothing but sulphur, and one was found filled with selenite crystals. About an acre of this bed had been removed when the locality was visited, and from this the superintendent estimated that one hundred barrels of pure sulphur had been obtained.

Wiedemann's Annalen der Physik und Chemie, No. 8.—Simple objective presentation of the Hertzian reflection experiments, by Victor Biernacki. The author places one of Lodge's "coherers" in the focal line of the secondary mirror. Under these conditions, mirrors with a length as small as 45 cm. and an aperture of 30 cm., with a focal length of 3 cm., exhibit the reflection phenomena well. The coherer employed is a horizontal glass tube filled with copper filings, whose resistance is reduced as soon as electric oscillations impinge upon it. The polarisation experiment is easily performed with a tiled wall, which behaves as a transparent solid to the electric rays. A striking experiment analogous to the introduction of a doubly-refracting crystal between two crossed nicolls is the introduction of a thick slab of good ice between the two crossed mirrors, with its axis of 45° to both the focal lines. The galvanometer connected with the coherer, which before was motionless, now gives a distinct reflection, thus showing the doubly-refracting nature of ice.—A convenient method for showing the electric refractive powers of liquids, by P. Drude. For this purpose, strong oscillations are necessary. These may be produced by a modification of Blondlot's arrangement, using an exciter without a condenser, whose total length is slightly smaller than half the wave-length required. The wave-lengths in water and other

...s are obtained by conducting the parallel wires through a long trough filled with the liquid. A bridge is put across them where they enter the water. Another bridge is placed on the wires in air on the other side of a Zehnder tube connected with a gold-leaf electroscope. This is shifted until the gold-leaves collapse. The distance between the two bridges is then, say, 30 cm. The bridge on the water's edge is then gradually shifted along the immersed wires, and the points at which the gold-leaves diverge and collapse are noted. The distance between two successive nodes is 4 cm., so that the refractive index of water for electric waves is 9, and the specific inductive capacity 81. Alcohol, glycerine, and other not very highly conducting liquids may be similarly investigated.—Inconstancy of spark potential, by G. Jaumann. The author shows that the potential which leads to a spark discharge depends upon several elements besides the thickness and nature of the dielectric, the chief one being the presence of variations of electric force, which hasten the discharge and lower the necessary difference of potential. When these variations are avoided, differences of potential amounting to several times the ordinary ones may become necessary for discharge. The spark gap is also affected by previous sparks and by a delay in discharging.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 16.—M. A. Cornu in the chair.—A memoir by M. F. V. Maquaire, on protection against naval collisions, was referred to a Committee.—The perpetual Secretary, in presenting vol. vi. of "Œuvres de Christiaan Huygens," reminded the Academy of the loss of M. Bierens de Hahn. The Haarlem Society will continue the publication of this work, so ably edited by M. Hahn.—On the "équilatères" included in the equations $O = \Sigma_1^{2n} - {}^2Z_1T_1^n \equiv H_n$, $O = \Sigma_1^{2n} - {}^1Z_1T_1^n \equiv H_n + \lambda H'_1$, by M. Paul Serret.—Researches on Algerian phosphates. The case of a phosphatic rock from Bougie, having the composition of a superphosphate, by MM. H. and A. Malbot. The results of a number of analyses of rocks from various sources are tabulated. The Bougie rock is described in detail, as it presents several peculiarities. With regard to the method of analysis, the conclusions are drawn: (1) The presence of organic matter may produce a loss when the phosphoric acid is estimated by direct precipitation as magnesium ammonium phosphate in citric liquor, and this error is not always diminished by a preliminary evaporation with nitric acid on the sand bath. (2) The same error does not occur if the phosphoric acid be first precipitated as ammonium phosphomolybdate. (3) The agreement between the two methods is exact when the organic matter is first destroyed by calcination at a red heat.—The neoformation of nerve cells in the brain of the monkey, following the complete ablation of the occipital lobes, by M. Alex. N. Vitzou, of Bucharest. A detailed account is given of the gradual recovery of the power of perceiving external objects by a monkey after complete ablation of the occipital lobes. An examination revealed the fact that the space formerly filled by the occipital lobes had been filled up by new tissue which was found to consist throughout of pyramidal nerve cells and nerve fibres, the cells being less numerous than in the ordinary occipital lobes of the adult. The new tissue was not due to hypertrophy of the anterior lobes. On repeating the ablation the monkey again lost the power of perceiving external objects, and is still under observation.—M. Ch. V. Zenger records in a note the occurrence of atmospheric disturbances at certain points in Central Europe on September 10 and 11, as predicted by him.

NEW SOUTH WALES.

Linnean Society, July 31.—Mr. Henry Deane, President, in the chair.—Catalogue of the described Coleoptera of Australia. Supplement, part i. *Cicindelidæ* and *Carabidæ*, by George Masters. It is proposed to give as far as possible a complete list of all the Australian Coleoptera described since the year 1886, also to fill in the omissions previous to that date. The present part contains references to 429 species, besides many corrections, and additional localities.—Australian *Termitidæ*, part i., by W. W. Froggatt. The author gives an account of the distribution of *Termites* in general and of the damage done by them, and passes on to a consideration of the habits and range of Australian forms, concluding with a general account of the structure of the termitaria of both the common mound-building species, and of those of *Eutermes* which form arboreal nests as well as on the ground. (*a*) Report on a fungus (*Meliola amphitricha*, Fries.) on *Dysoxylon*. The fungus is found on the leaves of *Dysoxylon rufum*, Benth., on the Richmond River, N.S.W., and has not previously been recorded for this colony. (*b*) Notes on *Uromyces amygdali*, Cooke—a synonym of *Puccinia pruni*, Pers.—Prune rust. This leaf rust is of great economic importance, since it attacks such valuable fruit trees as peach and nectarine, plum and apricot, cherry and almond, causing them prematurely to shed their leaves, and as a consequence, either to bear no fruit, or only small quantities of an inferior kind. Though sometimes called "Peach Yellows," it must not be confounded with the dreaded disease, due to bacteria, known by that name in the United States. Specimens of affected peach leaves, forwarded by Mr. Tryon from Queensland, yielded both uredospores and two-celled teleutospores. In Victoria in the summer season, even as late as July, only the uredospores are at all common. (*c*) Groundsel rust, *Puccinia erechtitis*, McAlp., with trimorphic teleutospores. The æcidial stage is common on groundsel; but this is the first record for teleutospores in Australia. The rust is identical with that on *Erechtites*, described last year. The specimens were procured at Hobart, Tasmania.—By D. McAlpine, Government Pathologist, Melbourne. (Communicated by J. H. Maiden). On a new species of *Elæocarpus* from Northern New South Wales, by J. H. Maiden and R. T. Baker. A large tree (height 80–100 feet, and a trunk diameter of 2–3 feet as seen), found on the Brunswick River. The affinities of this species lie between *E. sericopetalus*, F.v.M., and *E. ruminatus*, F.v.M.; it differs from these two species in the number of stamens, lobed petals, bracts, and fruits. It is named in honour of Mr. William Baeuerlen, Botanical Collector to the Technological Museum, Sydney.—On a new cone from the Solomon Islands, by John Brazier.

BRISBANE.

Royal Geographical Society of Australasia. Annual meeting, July 22. Mr. J. P. Thomson, President, in the chair.—The Secretary, Mr. J. Fenwick, read the yearly report of the Council, which stated that during the year sixteen ordinary members had been added to the roll of the Society. The library had received some valuable donations and exchanges, and the finances of the Society were in a satisfactory condition. The President read an address on the subject of the physical geography of Australia, after which the election of officers took place.

CONTENTS.

THURSDAY, OCTOBER 3, 1895.

RITTER'S "ASIA": RUSSIAN ADDENDA.

Eastern Siberia, including Lake Baikal and the Mountains on its North-Western Shore. Vol. II. By P. P. Semenoff, I. D. Cherskiy, and G. G. von Petz. Pp. 630. (Russian: St. Petersburg, 1895.)

THIS new volume, edited by P. P. Semenoff, from the MSS. of I. D. Cherskiy, and containing 630 pages of text, in lieu of the three paragraphs of Ritter's work, is even more interesting than the preceding volume, which was noticed in these columns a short time ago (NATURE, vol. l. p. 471). It covers Lake Baikal and the mountains along its north-western shore, and embodies explorations either entirely new or quite unknown even in Russia itself. Moreover, all that has been said concerning the preceding volume, as regards the masterly treatment of the subject and a strict adherence to Ritter's excellent methods—a combination of a minute description of details with broad generalisations drawn out of them—fully applies to this new instalment of the great work undertaken by the Russian Geographical Society. A third volume, containing Transbaikalia and the Gobi, will soon follow—the invaluable collaboration of M. Obrucheff having been secured for this purpose by the editor.

When we cast a glance upon a good orographical map of Asia (*e.g.* Petermann's, in Stieler's "Hand Atlas," or even in the miniature "Taschen Atlas" of the same publishers), we see that the two great plateaus of West and East Asia are fringed along their north-western borders with a chain of great lakes: the Caspian Sea, Lake Balkhash, Ala-kul and Zaisan, Ulungur, Baikal, and Oron; while a succession of large post-Tertiary lakes, now desiccated, which formerly filled the valleys of the Tian-shan, the Altais, the Sayans, and the Muya ridges, complete this chain of depressions along the outer border of the plateaus. Lake Baikal is one of the lakes of this chain—a small remainder only of the great mass of water which formerly filled up the valley of the Irkut, and the lower parts of the eastern tributaries of the present lake, and discharged its waters, as we now learn from the volume under review, through the narrow gorge pierced by the Irkut through the Tunka Alps, by means of which it now joins the Angara at Irkutsk. At that time, *i.e.* during the post-Tertiary period, its level stood, as shown by the lake deposits and terraces explored by Cherskiy, at least 928 feet above the present level of Lake Baikal, which now lies 1561 feet above the sea level.[1]

However, even in its present limits, Lake Baikal occupies the sixth place among the largest lakes of the globe (after Lake Tanganika), and the first place among the Alpine lakes. Sufficient to say that it covers 15,300 square miles, and that the two extremities of the crescent which it makes on a map are 380 miles distant from each other. As for its depth it stands foremost. Already Kononoff's soundings, in 1859, indicated a depth of 5621 feet, and when the Polish exiles, Dr. Dybowski and Godlewski, made, in 1867 and 1871–76, a series of very accurate soundings, they revealed the existence of several valleys in its bottom, attaining depths of 2197, 4460, and 4503 feet, the greatest depths being located in the proximity of the north-western shore, so that a depth of 1935 feet (374 feet below the level of the ocean) was found within a thousand metres from the coast.

Both in its position at the foot of, and the manner it penetrates at its southern extremity into, the plateau, Lake Baikal offers a striking analogy with the Caspian Sea. The same analogy appears in its relations to the surrounding mountains. It is divided about its middle by a submerged ridge, which appears on the surface in the Olkhon Island, and in the promontory of Svyatoi Nos; and of the two basins thus formed, and named respectively the "Great Sea" and the "Small Sea," the southern, that is the one which lies nearest to the plateau, is the deepest. In older works, and in some recent ones as well, Lake Baikal used to be described as a longitudinal valley between two parallel chains of mountains; but it is evident, from what has just been said, how false this view is. The next step would be to consider it as originated from two lakes which once occupied two longitudinal valleys, and joined together after the dividing ridge had been partially destroyed by geological agencies; and this hypothesis, too, has been advocated. Things appear, however, to be much more complicated than that. When I was working out a general scheme of the orography of Siberia, I was compelled to recognise that even the two-valleys-hypothesis could not interpret the real features of the region, and although at that time (1872) we knew next to nothing about the geological structure of the Baikal mountains, I was induced, by considerations about the structure of the plateaus, their border-ridges, and the Alpine chains parallel to the latter, to draw two chains across the northern part of the lake. From the volume under review, we now learn the real state of affairs. In all his explorations in Siberia, Cherskiy used to pay a great deal of attention to the orographical features as they *now* appear to the explorer, and tried to discriminate in how far they were a result of structural features—foldings of the rocks and so on—and in how far they were derived from subsequent erosion which has been going on in these parts of Siberia since the Silurian and Cambrian periods, when the mountain ridges and plateaus received their first shape. As regards the Baikal mountains, it now appears that there is, on the north-western shore, a real ridge running parallel to the shore, and separated by a valley from the mountains lying further west; but that both this ridge and the deep hollow of the Baikal are due, not to structural, but to erosion processes. The ridge consists of slates and gneisses *crossing* it in a diagonal direction, and these strata cross also the northern part of the lake in the same direction—the direction I had indicated on the orographical map on merely theoretical grounds—so as to reappear in the same succession on the eastern shore. The foldings of the Baikal Mountains date from the Silurian, Cambrian, or perhaps even the Laurentian period (Devonian red sandstones lie undisturbed at the outer footings of the Baikal Mountains), but subsequent

[1] There is still a certain uncertainty, perhaps of over 100 feet, concerning the altitude of the level of Lake Baikal. A levelling across Siberia had been made a few years ago; but the death of the person who undertook the calculation of the results brought about some confusion, and Russian geographers suppose that some considerable error may have crept in in the levelling between the Yenisei and Irkutsk, and consequently in the above figure.

A A

erosion and denudation have modified the primary features on a gigantic scale; and a valley so deep as the northern part of Lake Baikal is, has been dug out *across* the former direction of the chains. The lake is thus an immense erosion valley which only partially has been determined by the structural valleys at the foot of the plateau, but has received its final shape through erosion, which made several parallel lakes coalesce as the mountains once separating them were pierced through and obliterated.

This instance will already give an idea of the interest which attaches to the volume now published, and the wealth of data which will be found in it. We sincerely desire, in the interests of geography, that at least these new volumes of the series should be rendered accessible to West European geographers.

The described region is very thinly populated, and contains but few explored remains of the past. As to its flora, it has been properly explored only on the Olkhon Island. The little, however, which is known in these two directions is well summed up, and will give a sound basis for ulterior exploration. We hope to find in the forthcoming volume a summary of all that is known about the fauna of the lake. P. K.

APPLICATIONS OF BESSEL FUNCTIONS.

A Treatise on Bessel Functions and their Applications to Physics. By Andrew Gray, M.A., and G. B. Mathews, M.A. (London: Macmillan and Co., 1895.)

THIS book, like the kindred work of Prof. Byerly on "Fourier's Series and Spherical Harmonics," marks the modern system of mathematical treatment, and may be contrasted with Dr. Todhunter's "Functions of Laplace, Lamé, and Bessel," of twenty years ago. At that time it was considered desirable to develop the purely mathematical analysis quite apart from the physical considerations to which it owed its life and interest; keeping the pure and the mixed mathematics in separate water-tight compartments, so to speak, with an impenetrable bulkhead between.

But as the Bessel function, like every other function, first presented itself in connection with physical investigations, the authors have done well to begin, on p. 1, with a brief account of three independent problems which lead to its introduction into analysis, before entering upon the discussion of the properties of the Bessel functions.

These three problems are: the small oscillations of a vertical chain, the conduction of heat in a solid cylinder, and the complete solution of Kepler's problem by expressing radius vector, true and excentric anomaly in terms of the mean anomaly.

It is very extraordinary that Kepler's problem should, as a general rule, be still left unfinished in the ordinary treatises, considering that the Bessel function is implicitly defined in the equation; but we need go back only twenty-five years, and we find Boole's "Differential Equations" ignoring the Bessel Function and the solution of the general Riccati equation which it provides. In those days it was customary to speak of any solution, not immediately expressible by algebraical or trigonometrical functions, as "not integrable in finite terms"; an elliptic integral was skirted round with the remark that it was "reducible to a matter of mere quadrature," and even the homely hyberbolic functions were tabooed.

String is the favourite material of the mathematician for illustrating catenary properties; but it is a relief to find that the authors have provided a *chain* for the discussion of the oscillations when suspended in a vertical line. The banal word *string* turns up accidentally two or three lines lower down (line 10, p. 1), but if a piece of string is used by the side of a length of fine chain, such as is now purchasable, the unsuitability of the string, by reason of its lack of flexibilty and its kinkiness, for the representation of catenaries and their oscillations, is at once manifest.

The small plane oscillations of the chain about its mean vertical position are of exactly the same character as the slight deviations from the straight line due to spinning the chain from its highest point of suspension; and this procedure has the advantage of showing a permanent figure, similar to that given for $J_0(\sqrt{x})$ on p. 295 of Lamb's "Hydrodynamics"; with a little practice the knack of producing one, two, three or more nodes at will is easily attained. Thus with a piece of chain 4 feet long, the number of revolutions per second should be 0·54, 1·24, 1·95, 2·65, &c.

The Bessel function was first introduced by the inventor for the complete solution of Kepler's problem, namely, to express the variable quantities in undisturbed planetary motion in terms of the time or mean anomaly $\mu = nt + \epsilon - \varpi$.

The authors avoid the awkward integration by parts employed by Todhunter in determining the excentric anomaly ϕ by means of a differentiation. Another procedure will give a/r, where a denotes the mean distance and r the radius vector, more directly, from the relation

$$\phi = \mu + e \sin \phi.$$

For differentiation with respect to μ gives

$$\frac{d\phi}{d\mu} = \frac{1}{1 - e\cos\phi} = \frac{1 + e\cos\theta}{1 - e^2} = \frac{a}{r} = 1 + \Sigma \mathrm{B}_r \cos r\mu,$$

suppose, when expressed in a Fourier series, and then

$$\mathrm{B}_r = \frac{2}{\pi}\int_0^\pi \cos r\mu \frac{d\phi}{d\mu} d\mu = \frac{2}{\pi}\int_0^\pi \cos r(\phi - e\sin\phi) d\phi = 2\mathrm{J}_r(re),$$

according to Bessel's definition.

An integration now gives

$$\phi = \mu + 2\Sigma \frac{\mathrm{J}_r(re)}{r} \sin r\mu$$

and

$$\sin\phi = \frac{\phi - \mu}{e} = 2\Sigma \frac{\mathrm{J}_r(re)}{re} \sin r\mu ; \text{ \&c.}$$

Chapters ii.-ix. are devoted to the purely analytical development of the Bessel function, considered as the solution of a differential equation, as an algebraical or trigonometrical series, or as a definite integral; these are the earlier chapters for which the authors apologise in the preface as appearing to contain a needless amount of tedious analysis. In Prof. Byerly's treatise the requisite analysis is introduced in small doses, and only as required; but the ordinary mathematician loves to strew the path at the outside with difficulties best kept out of sight; thus, as Heaviside remarks, the too rigorous mathematician tends to become obstructive. It is of

course reassuring to know that the functions employed in the physical applications, rest on a sound analytical basis, and that the convergency of the series has been carefully examined. But there is no compulsion to follow these demonstrations, tedious to all but pure mathematicians; so we can pass on direct to Chapter x., where the physical interest is resumed, under the head of "Vibrations of Membranes," for instance the notes produced on a circular drum-head. Lord Kelvin's oscillations of a columnar vortex, Lord Rayleigh's waves in a circular tank, and Sir George Stokes's investigation of the drag of the air in pendulum vibrations, make up an interesting Chapter xi. on Hydrodynamics.

Chapter xii. deals with the steady flow of electricity or of heat, and Chapter xiii. with the fascinating and novel phenomenon of Hertz's electromagnetic waves, when propagated along wires, in which problem the Bessel function assumes an essential importance.

The Diffraction of Light, considered in Chapter xiv., contains important applications of the Bessel functions; the hydrodynamical analogue would be the investigation of the effect of a breakwater in smoothing the waves which bend round behind into its shelter; for instance, the effect of the Goodwin Sands on the safe anchorage in the Downs.

Newton rejected the Undulatory Theory of Light, partly because he could not understand the existence of shadows on this hypothesis, a curious effect of Newton's early ideas as a country boy; had he been brought up on the sea coast, this apparent difficulty could not have troubled him.

It would be a needless complication to consider any but straight waves in the case of the breakwater; and similarly in the Diffraction problem, the authors might have made a simplification by parallelising the incident light by passing it through a lens; or at least this special case, which is the one of practical importance in the subsequent discussion of the resolving power of a telescope, might receive separate treatment as the analysis now becomes almost self-evident. This chapter concludes with a discussion of Fresnel's integrals, required in the diffraction through a narrow slit; the integrals are expressed by a series of Bessel Functions of fractional order, half an odd integer, and are represented graphically by Cornu's spirals.

The problem of the stability of a vertical mast or tree, considered under the head of Miscellaneous Application in the last chapter, may well be amplified by examining the effect of centrifugal whirling on the stability, as in the case of the chain on p. 1; for the number of revolutions required to start instability is exactly equal to the number of vibrations which the mast or tree will make when swaying from side to side. A differential equation of the fourth order, with a variable coefficient, now makes its appearance, the solution of which will express the oscillations of the bullrushes in a stream, or the waving of cornstalks in a field. The curious appearance of permanence in the waves on a cornfield gives an illustration, analogous to Prof. Osborne Reynolds's disconnected pendulum, of a case of zero group-velocity; and by some intuitive deductions from the appearance of these waves the farmer can judge the time suitable for harvest.

The authors have been fortunate in securing an original collection of numerical tables, including those of Dr Meissel, who did not live quite long enough to see his valuable calculations published in this book.

A collection of examples adds greatly to the interest of the treatise, and will probably form the nucleus of a still larger list in the future.

Altogether the authors are to be congratulated in bringing their task to such a successful conclusion; and they deserve the gratitude of the mathematical and physical student for their lucid and interesting mode of presentment.

A. G. Greenhill.

OUR BOOK SHELF.

Protoplasme et Noyau. Par J. Pérez, Professeur à la Faculté des Sciences de Bordeaux. (Bordeaux: Imprimerie G. Gounouilhou, 1894.)

Experimental work in recent years has repeatedly shown that in plants as well as in animals the physiological *rôle* of the nucleus in the cell is one of great importance. It has been demonstrated that non-nucleated fragments of protoplasm, whether of a *Spirogyra* or an Infusorian, are incapable of growth and reproduction; while, on the other hand, fragments containing a portion of nuclear material are capable of complete recrescence. Impressed by these facts the writer of the essay before us has been led to doubt whether protoplasm can be properly regarded as the "physical basis of life," since it cannot retain its life when removed from the influence of the nucleus. Consistently with this position the writer throws doubt upon the existence of non-nucleate organisms in general. The presence of nuclei has been demonstrated in many forms once believed to be destitute of them—*e.g.* Mushrooms, marine Rhizopods, and plasmodia. There remains only Haeckel's group of Monera in which the presence of a nucleus may still be disputed. M. Pérez considers in turn each of Haeckel's subdivisions of this most artificial group. In the Lobomonera (*e.g. Protamœba*) he believes that the nucleus has been overlooked. In the Rhizomonera the nucleus has been observed in various species of *Vampyrella*; and it probably exists also in *Protomyxa*, since this form produces zoospores; the zoospores of those Myxomycetes which most resemble *Protomyxa* have been shown by Zopf to be nucleated. In the Tachymonera (Schizomycetes) the greater part of the body seems to consist of nucleoplasm, while the zooglœa may perhaps be compared with the undivided protoplasm of a plasmodium.

M. Pérez concludes that non-nucleated organisms or cytodes are creations of the imagination; that protoplasm, by which our author means cytoplasm, is not the primitive living matter, but a product of nucleoplasm; and that nucleoplasm, and not protoplasm, is the most primitive living substance known to us.

Analytical Key to the Natural Orders of Flowering Plants. By Franz Thonner. Small 8vo. pp. 151. (London: Swan Sonnenschein and Co., 1895.)

The author's apology for his little book is that few "Exotic Floras" contain artificial keys to the natural orders, even such as contain keys to the genera and species. But we imagine few persons would attempt working with a flora, exotic or native, without some preliminary knowledge of botany, and especially of the natural orders. Indeed a considerable acquaintance with the subject would be necessary to enable a person to use the present key to advantage. For example, the author begins with "ovules naked," and "ovules enclosed in an ovary," &c. Now, to be able to decide this point means a great deal, for a person who could do it would most likely know his gymnosperm without looking at the ovule

—even better without, perhaps. The next alternative is between isolated vascular bundles, and vascular bundles in a cylinder, connected with other characters, entailing previous teaching and study, which should largely consist of acquiring a knowledge of natural orders. Nevertheless this book may prove useful, especially to the collector desirous of determining the natural orders of his plants in the field or at home. So far as we have tested it, it is carefully compiled and edited, and we can conscientiously recommend it to those who know the characters of many natural orders in advance.

Attempt to Liquefy Helium.

I HAVE received a letter from Prof. Olszewski, of Krakau, in which he informs me that having exposed a sample of helium which I sent him to the same treatment as was successful in liquefying hydrogen—namely, compressing with a pressure of 140 atmospheres, cooling to the temperature of air boiling at low pressure, and then expanding suddenly—he has been unable to detect any sign of liquefaction.

The density of helium being, roughly speaking, twice that of hydrogen, it is very striking that its liquefying point should lie below that of hydrogen. It may be remembered that argon, which has a higher density than oxygen, liquefies at a lower temperature than oxygen; and it was pointed out by Prof. Olszewski that this behaviour was not improbably connected with its apparently simple molecular constitution. The similar fact now recorded for helium may therefore be regarded as evidence of its simple molecular constitution. I use the word "its" instead of "their," although further research may corroborate Prof. Runge's contention that what is termed helium may in reality be a mixture of two, if not more than two elements. If this contention is true, both, or all, must have extraordinarily low boiling-points.

WILLIAM RAMSAY.

September 23.

Helium and the Spectrum of Nova Aurigæ.

IN the paper on the constituents of the gas in cleveite that we read before the British Association, we said that in the first spectrum of Nova Aurigæ the principal lines 5016 and 4922 of the lighter constituent were far more intense than those of the other constituent. But we were puzzled at the line 6678 not having been observed, as it is also a strong line in the spectrum of the lighter constituent. On inquiry, Dr. and Mrs. Huggins were kind enough to give us better information. Dr. Huggins writes:

"I think there is no doubt that we did see the red line at 6678 in Nova Aurigæ. We were unable to measure in that part of the spectrum, but on three nights we saw a bright line a little below C. This was a pure estimation under difficult circumstances. In the map we put the line, as a mere guess, at a little over 6700. On the first night we put the line in a rough diagram, made at the time, a little nearer C, almost exactly at 6678. On a subsequent night, we made the estimation a little below 6700, but the line was not then so bright."

London, September 27. C. RUNGE AND F. PASCHEN.

Latent Vitality in Seeds.

THERE is no doubt, as M. Casimir de Candolle has recently shown in his paper on latent life in seeds, that all the functions of seeds may remain completely quiescent for a long period; probably in some cases this period may be indefinitely long. In 1878 I published a paper[1] on the resistance of seeds, especially of *Medicago sativa*, or lucerne, to the action of gaseous and liquid chemical reagents. An abstract of my experiments was published in NATURE, vol. xxv., 1882, p. 328.

Recently I have examined portions of the seeds used in the experiments of 1877 and 1878, to see if after the lapse of so many years, during which the seeds have remained constantly surrounded by special gases, or immersed in different solutions, they had retained their vitality. The results have been remarkable, for in some cases a large proportion of the seeds have maintained their vitality after a lapse of 15, 16, and nearly 17 years of special external chemical conditions. I summarise the results of some of my experiments.

(*a*) *Experiments in Gases.*

In all these experiments the gases were *dry*, for in these conditions moisture is rapidly fatal to the seeds. The seeds were introduced into small bulbed tubes, into which the dry gas was made to pass for some time, after which the tubes were rapidly sealed at a spirit-lamp flame. The tubes were then kept in the dark.

In the following summary I give the dates of the sealing and opening of the tubes:—

Hydrogen.—Lucerne seeds, from September 15, 1877, to August 5, 1894, a period of 16 years, 10 months, and 20 days. Out of 51 seeds sown, none germinated. Seeds of wheat, vetch, *Cynara cardunculus* and coriander, kept in hydrogen, gave the same negative results. There is some suspicion that the hydrogen had not been originally well dried.

Oxygen.—Lucerne, from May 19, 1878, to August 4, 1894, 16 years, 2 months, and 15 days. Out of 293 seeds sown, 2 germinated, or 0·68 per cent. The seeds were not thoroughly dry.

Nitrogen.—Lucerne, from April 12, 1878, to August 21, 1894, 16 years, 3 months, and 22 days. Out of 320 seeds, 181 germinated, or 56·56 per cent.

Chlorine and Hydrochloric Acid Gas.—Lucerne, from April 28, 1878, to August 3, 1894, 16 years, 3 months, and 5 days. Out of 342 seeds, 23 germinated, or 6·72 per cent. Originally these seeds had been put into pure chlorine; but the gas had acted on the seeds, carbonising a portion of them, so that at the end of the experiment the seeds were in an atmosphere composed chiefly of hydrochloric acid gas, mixed with carbon dioxide.

In a second experiment with lucerne seed, kept in chlorine, and then hydrochloric acid, during the same period, out of 167 sown, 10 germinated, or 5·98 per cent. In this experiment the tube was carefully opened *in vacuo*, to protect the seeds from the moisture condensed by the hydrochloric acid gas at the moment when it is brought into contact with common air.

Sulphuretted Hydrogen.—From October 14, 1877, to August 5, 1894, 16 years, 9 months, and 22 days. After the opening of the tube, filled with the strongly smelling gas, the seeds were left in contact with the air for 24 hours, before sowing them in the moist sand of the germinator. Out of 101 lucerne seeds, one germinated, or 0·99 per cent. Out of 50 seeds of wheat, none germinated.

Arseniuretted Hydrogen.—From April 4, 1878, to August 4, 1894, 16 years and 4 months. On opening the tube the garlic smell of AsH_3 was strongly evident. Out of 255 lucerne seeds sown, 181 germinated, or 70·98 per cent. In a second experiment with seeds kept in arseniuretted hydrogen, out of 247 lucerne seeds 170 germinated, or 68·82 per cent.

Carbon Monoxide.—From April 3, 1878, to August 4, 1894, or 16 years and 4 months. Out of 266 lucerne seeds, 224 germinated, or 84·2 per cent.

Carbon Dioxide.—From September 8, 1877, to August 5, 1894, or 16 years, 11 months, and 27 days. The same tube contained seeds of lucerne, wheat, vetch, *Cynara*, and coriander. None germinated. Perhaps the large number of seeds contained in a relatively small tube rendered the carbon dioxide damp, and therefore noxious.

Nitric Oxide.—From May 2, 1878, to August 4, 1894, or 16 years, 3 months, and 2 days. On opening the tube, abundant red fumes were produced by contact with air. Before sowing, the seeds were left dry for 24 hours. Some of the seeds were brownish, the rest retained their natural colour. Out of 309 lucerne seeds, 3 germinated, or 0·97 per cent. In a second experiment, the tube containing the lucerne seeds was opened *in vacuo*: out of 320 seeds, 2 germinated, or 0·62 per cent.

[1] [illegible] "Resistenza di alcuni semi all' azione prolungata di agenti [illegible] liquidi," *Gazzetta Chimica italiana*, ix., 1879, p. 199; and [illegible] *ital.* [illegible], 1879, p. [illegible]

(*b*) *Experiments with Liquids and Solutions.*

I give only the results obtained with alcohol and alcoholic solutions. In other liquids, such as ether and amyl alcohol, the liquids had gradually evaporated, so that the exact period of their action could not be ascertained, and the seeds, covered with a moist oily varnish, had lost all vitality. Lucerne seeds kept in chloroform for 16 years and 4 months, were completely lifeless. In all the recorded experiments the seeds were completely immersed in a relatively large volume of liquid.

Strong Alcohol.—From March 26, 1878, to August 6, 1894, or 16 years, 4 months, and 13 days. The alcohol was originally absolute, but in contact with the seeds, and during so many years must have absorbed a small proportion of water. Before being sown, the lucerne seeds were carefully air-dried on a filter for 12 hours. Out of 60 seeds sown, 40 germinated, or 66·6 per cent.

Concentrated Alcoholic Solution of Corrosive Sublimate.—The alcoholic solution was originally prepared with alcohol nearly absolute, and saturated with mercuric chloride. From May 23, 1878, to August 17, 1894, or 16 years, 2 months, and 25 days. On taking the seed from the mercuric solution, they were very carefully washed with alcohol at 97 per cent. until every trace of the mercuric compound was washed away. The seeds were dried at the ordinary temperature, and then sown. Out of 79 lucerne seeds, 16 germinated, or 20·2 per cent.

Alcoholic Solution of Sulphur Dioxide.—From November 10, 1878, to August 24, 1894, or 15 years, 9 months, and 14 days. Originally the alcohol was of 93 per cent. strength; the solution preserved a suffocating odour of sulphurous acid. The lucerne seeds were mixed with minute sulphur crystals; the seeds were well washed with strong alcohol, dried and sown. Out of 645 lucerne seeds, one alone germinated, or 0·15 per cent.

Alcoholic Solution of Sulphuretted Hydrogen.—From November 10, 1878, to September 4, 1894, or 15 years, 9 months, and 15 days. The alcohol, originally 93 per cent. strength, had been repeatedly saturated with sulphuretted hydrogen gas. The liquid emitted a marked mercaptanic smell. Sulphur crystals were formed, and sedimented with the lucerne seeds. The latter were washed with 97 per cent. alcohol, and then air-dried. Out of 583 seeds, 41 germinated, or 7·03 per cent.

Alcoholic Solution of Nitric Oxide.—From November 10, 1878, to September 4, 1894, a period equal to that of the last described experiment. The alcohol, 93 per cent. strength, had been repeatedly saturated with NO. Before sowing, the seeds were washed with alcohol and dried. Out of 288 seeds, 12 germinated, or 4·16 per cent.

Alcoholic Solution of Phenol.—The lucerne seeds preserved in the solution for over 15 years, showed no signs of vitality. In washing the seeds, previous to sowing, with alcohol, they could not be completely purified from the phenol.

Many of the germinating lucerne plants developed from the seeds used in these experiments, were transplanted from the germinator into flower-pots. The plants grew well, and have flowered and seeded normally.

At the beginning of these experiments, in 1877 and 1878, I was not aware of the noxious action of even small proportions of moisture. It is probable that if in all these experiments special care had been taken at the beginning to exclude as much as possible moisture, both from the seeds and from the gases or liquids, a much larger proportion of seeds would have retained their vitality. The difficulty of preserving the vitality of large seeds must be chiefly caused, in all probability, by the difficulty of thoroughly drying them.

These experiments are of interest in showing that seeds may retain their vitality in conditions when all respiratory exchange is completely prevented for a long series of years. They fully confirm the results of the late G. J. Romanes, who proved that seeds may preserve their vitality for 15 months when kept *in vacuo*, or when transferred from the vacuum tubes to other tubes, charged with sundry gases or vapours.[1]

My experiments encourage, moreover, the suspicion that latent vitality may last indefinitely when sufficient care is taken to prevent all exchange with the surrounding medium. There is no reason for denying the possibility of the retention of vitality in seeds preserved during many centuries, such as the mummy-wheat, and seeds from Pompei and Herculaneum, provided that these seeds have been preserved from the beginning in conditions unfavourable to chemical change. The original dryness of the seeds, and their preservation from soil moisture or moist air, must be the very first conditions for a latent secular vitality.

In experimenting with seeds from Pompei and Herculaneum, I have not as yet been able to find among them any living grain. The greater part of these seeds are too much carbonised and changed to permit the entertaining of much hope as to their possible vitality. Especially among the seeds of Pompei, the carbonisation must have been caused by the slow action of moisture, which would speedily destroy all life in the seeds. Among the Pompeian wheat the destruction of organic matter has been so great as to leave in the seed, in its present condition, a proportion of ash as high, in some cases, as 4·2 per cent., and even 8·4 per cent.

On the other hand, some of these seeds, as those found in the granaries of the *Casa dell' Argo*, at Herculaneum, in 1828, seem to have been in conditions favourable to a prolonged preservation of latent vitality; the millet seeds, especially, were found unchanged in outer aspect. Unfortunately, no test was made at the time of their discovery, and since then the action of moist air, and exposure to changes of temperature and to light, must have impaired fatally any remnant of vitality still lurking amongst the seeds.

All researches on latent life are of great interest in ascertaining the nature of living matter. The present researches have established that, for some seeds at least, respiration, or exchange with the surrounding medium, is not necessary for the preservation of germ-life. It is a common notion that life, or capacity for life, is always connected with continuous chemical and physical change. The very existence of living matter is supposed to imply change. There is now reason for believing that living matter may exist, in a completely passive state, without any chemical change whatever, and may therefore maintain its special properties for an indefinite time, as is the case with mineral and all lifeless matter. Chemical change in living matter means active life, the wear and tear of which necessarily leads to death. Latent life, when completely passive, in a chemical sense, ought to be life without death.

It may be finally remarked that the proof of the resistance of seeds to vacuum, of the non-necessity of a respiratory exchange with outer air, together with the proof of the resistance in some seeds to very low temperatures, are facts encouraging the belief that the origin of life on our globe may be due to the introduction of germs that have travelled, embedded in aerolites, from other planets where life is older than upon the earth.

ITALO GIGLIOLI.

Regia Scuola Superiore d'Agricoltura,
Portici, near Naples.

To Friends and Fellow Workers in Quaternions.

SINCE the publication of Hamilton's "Elements of Quaternions," in which the great mathematician developed his new calculus with admirable skill and clearness, more than thirty years have passed away, without it finding the adequate recognition which it so highly deserves. The circumstance is still the more deplorable as the calculus has since been further developed by Prof. Tait and others.

There is, in truth, no question as to the importance of the use of vectorial quantities in physics, but on account of their apparently preponderating importance, various physicists have been led to invent new forms of vector-theory excluding the idea of quaternions. But, as far as we see, they are founded on definitions which are established by quaternions, and are systems of notation rather than logical developments of a mathematical idea.

On the other hand, many who are prejudiced against the calculus of quaternions maintain the opinion that it is hard to understand, and that it contains a great deal which is useless in addition to things immediately applicable. To the latter charge there need be no answer, since all forms of mathematics are exactly alike in this respect, and since in the very combination of the pure and the applied lies the potentiality of further development. In regard to the former objection, quaternionists need only say that if the objectors approach the calculus of quaternions with proper care and meekness, they will ere long assuredly rejoice in having at their disposal an instrument of research mightier far than they had the slightest notion of so long as they were in the domain of cartesian coordinates. Certainly it would be a blessing to science if they could accept these assertions, and their endeavours would find a

[1] NATURE, December 7, 1893, p. 140.

... in the advancement wherever this method might be applied. So much for these objections.

New notations in the calculus of quaternions must needs be invented from time to time. But since they are becoming complex (though far simpler than in cartesian coordinates) as the problems are getting more complicated, it is highly desirable already at this stage of development, to exchange opinions on the selection or adoption of new symbols.

By these and other considerations we have been led to believe that the time has come for those who are interested in vector analysis to come to the fore and join hands. In order to further this purpose, we venture to suggest the establishing of something like an "International Association for Promoting the Calculus of Quaternions." The following would be amongst its principal objects:

(1) That the members should be informed of the publications of all important papers and works respecting either the theory of quaternions or its applications; and if possible to have these made accessible to them.

(2) That the members should be afforded the means of exchanging opinions on the introduction and adoption of new notations.

In these few lines we have tried to point out the important tasks of the Association, but shall be obliged for any suggestion or improvement. All we desire is to assure to the calculus the place it deserves, and consequently to see it fully developed in its various aspects by the combined efforts of able mathematicians and physicists. It is almost needless to say that we are only preparing the way: and once the Association has been started, we shall be ready to place it in the hands of persons much more competent than ourselves to further its best interests.

We earnestly hope that all friends will appreciate our endeavours and show us at once some token of approval. We would ask those who are in Europe to communicate with the first of the names below, and those in America with the second.

P. MOLENBROEK, The Hague, Holland.

SHUNKICHI KIMURA, Yale University, U.S.A.

August 7.

P.S.—It has been suggested by friends interested in this matter to enlarge the scope of the proposed Association so as to include all systems allied to quaternions and to Grassmann's "Ausdehnungslehre." This suggestion we are in full sympathy with. The name of the Association might then be "The International Association for Promoting the Study of Quaternions and Allied Systems of Mathematics." P. M.

Artificial Human Milk.

It is stated in NATURE of September 19, that "so far, according to Dr. Backhaus, no satisfactory substitute has been produced in the place of human milk"; and a method is then described by which he has "quite recently" succeeded in supplying the deficiency. It appears to differ little from the process first employed and made known by me in 1854, and afterwards published in my "Experimental Researches" in 1877; except that, in omitting to add the necessary amount of milk-sugar to make up for the deficiency in the cow's milk, Dr. Backhaus fails to obtain an artificial milk closely resembling the human in chemical composition.

My recipe has, since its first publication, been advantageously used in private and hospital practice by the late Prof. W. C. Williamson, by Dr. W. Playfair, and others, but it has probably not come under the notice of Dr. Backhaus.

My process is based on the fact that by the removal of one-third of the casein from cow's milk, and the addition of one-third more milk-sugar, a liquid is obtained which closely approaches human milk in composition. The following is the mode of preparing the milk, and it is so simple that any intelligent mother or nurse can easily carry it out.

"Allow one-third of a pint of new milk to stand for about twelve hours, remove the cream, and add it to two-thirds of a pint of new milk, as fresh from the cow as possible. Into the one-third of a pint of blue milk left after the abstraction of the cream, put a piece of rennet about one inch square. Set the vessel in warm water until the milk is fully curdled, an operation requiring from five to fifteen minutes, according to the activity of the rennet, which should be removed as soon as the curdling commences, and put into an egg-cup for use on subsequent occasions, as it may be employed daily for a week or two. Break up the curd repeatedly and carefully separate the whole of the whey, which should then be rapidly heated to boiling in a small tin pan placed over a spirit- or gas-lamp. During the heating, a further quantity of casein separates, and must be removed by straining through muslin. Now dissolve 110 grains of powdered milk-sugar in the hot whey, and mix it with two-thirds of a pint of new milk to which the cream from the other third of a pint was added, as already described. The artificial milk should be used within twelve hours of its preparation: and it is almost needless to add, that all the vessels employed in its manufacture and administration should be kept scrupulously clean."

In this process only one-third of the milk was sterilised; but, in the light of modern bacteriology, it is desirable to sterilise the whole by finally heating it to boiling.

The Yews, Reigate, September 20. E. FRANKLAND.

The Elements of Architecture.

HAVING been for some weeks out of the way of seeing papers, I have only just seen the review of "Architecture for General Readers" in NATURE of August 15. I ought to thank you for devoting so much space to a book which deals rather with art than "nature," and there are one or two criticisms on special points which I think are just, and which will have attention in the second edition of the book. But there are three remarks of the reviewer's on which I should like to have a word.

(1) He refers the reader to Perrot and Chipiez' work on "The Arts of Primitive Greece" for proof of the derivation of the Greek entablature from a wooden origin. In my opinion, Messrs. Perrot and Chipiez prove nothing whatever but their own ingenuity. They argue in a circle. Assuming the probability of a wooden origin for the Greek entablature, they proceed to construct out of their own inner consciousness a series of wooden structures, quite possible but entirely imaginary, in which the origin of all the features of the stone entablature is carefully provided for, and then produce an engraving of the stone (or, rather, marble) entablature to show triumphantly the result which they have been consciously leading up to all the way. You may prove anything on that kind of principle. I do not deny that the Greek entablature appears to be of timber origin. I only say it has not been proved to be so, and I am sure Messrs. Perrot and Chipiez have not proved it.

(2) The reviewer thinks I am captious in objecting to Wren's double cupola at St. Paul's as a sham, and that I might as well object to the vault which hides the interior of the tower over the crossing in a mediæval cathedral. But he misses the main point of my objection, which is that the exterior timber dome of St. Paul's is made to appear, to the eye, to carry a ponderous stone lantern which would, in fact, crush it at once, and which is really the termination of a concealed masonic construction thrusting itself through the timber dome. At Florence and St. Peter's the stone lantern is really carried by the visible dome which appears to carry it: at St. Paul's it is not, and could not be. I consider St. Paul's by far the more beautiful design of the three, but it cannot be denied that it is a constructional falsehood in that respect. (See the block section of it given on p. 99 of the book.)

(3) The reviewer objects that I have denied to Italy any specimen of true Gothic, and yet that Milan is one of the most impressive Gothic interiors in existence. This may be true as to general effect; but the detail of Milan is wretched; and it is by detail that purity of architectural style is chiefly to be judged.

H. HEATHCOTE STATHAM.

(1) MR. STATHAM objects to Perrot and Chipiez' work, on primitive Greece being cited for proof of the derivation of the Greek entablature from a wooden origin.

It seems to me that in this matter possibly the main difference between Mr. Statham and the reviewer lies in the meaning to be attached to the word *proof*. Absolute mathematical proof is seldom to be looked for in archæological or historical descriptions, and we must be often contented with a sufficiently high probability. Taking the word in that sense, it seems to me that the circle in which Perrot and Chipiez are said to argue, cannot be made to re-enter into itself.

Mr. Statham allows that the Greek entablature "appears to be of timber origin." Vitruvius (iv. cap. 2) says distinctly that it

was so. The remains of primitive architecture in Greece—particularly at Tiryns—show that wood must have entered largely into architectural constructions; amongst other evidences, the traces of wooden door-cases cannot be explained away. Perrot and Chipiez, with whatever amount of fancifulness there may be (and there is no doubt much which is altogether hypothetical) in their restorations, do come legitimately to an explanation of the Doric guttæ both under the triglyphs and beneath the mutules, as typical of the ends of wooden pegs or trenails in timber construction, which is sufficient for the argument in the review, in which there was no intention to approve Perrot and Chipiez' restorations and deductions any further than that.

(2) As to the second objection taken to the review—the remark respecting the cupola of St. Paul's. The remark in the review had reference to the objection that the external outline of the dome was distinct from the internal, and not to the question of support of the lantern; but with reference to the latter point, when the lantern of St. Peter's is quoted as supported by a more legitimate construction than that of St. Paul's, it may be asked: Why the construction of St. Peter's dome, which is absolutely dependent for its safety on the iron chains by which it is hooped together, is preferable to that of St. Paul's, where the lantern has a much securer, and therefore not less legitimate, support in Sir Christopher Wren's cone?

(3) One remark only on the objection raised to the style of Milan Cathedral. The detail is said to be wretched. That it does not conform to the canon of Northern Gothic can be readily conceded, but that the shafts of the magnificent forest of pillars which support the interior are wretchedly designed, and unsuitable to the intended effect, is not so easy to admit.

THE REVIEWER.

Do the Components of Compound Colours in Nature follow a Law of Multiple Proportions?

THIS question, put by Mr. F. Howard Collins in NATURE (p. 438), may be answered in the negative.

In practical work there is no indication of such a law. It is found that the two rays, which together produce a compound natural colour, may be in any proportions; when there is a multiple proportion, and in some cases there must be, it is only as forming part of a series of variations, such as are frequently found within the limits of a single popular colour term. How wide these proportions may be, can be illustrated by comparing them to the varying proportions of two irregular curves towards each other.

The examples of foliage quoted can only be taken as representing individual instances. Variations of climate, age, cultivation, and aspect alter the colour proportions of a given variety of leaf; indeed, such variations are sometimes found in the same leaf. JOSEPH W. LOVIBOND.

Salisbury, September 23.

IN view of the letters, recently printed in NATURE, by Mr. H. H. Pillsbury and Mr. Herbert Spencer, it may be well to state that Chevreul published an "Exposé d'un moyen de définir et de nommer les couleur d'après une méthode précise et expérimentale" (Paris, 1861, also *Mém. de l'Acad.* xxxiii.), in which elaborate charts are given showing the colours defined by a decimal system and in ten degrees of saturation.

Recently Prof. W. Hallock, of this College, has painted discs with standard colours, and determined their wave-lengths with the spectroscope. These discs were then used to study 6000 samples of coloured objects, and formulæ were determined for some 500 named colours. These formulæ have been used for defining the names of colours in the new "Standard Dictionary" (Funk and Wagnall's, New York).

A Problem in Thermodynamics.

IT may interest some of your readers to know that the problem in thermodynamics, propounded by Mr. Blass in your number of August 29, has actually been put to the test. I pointed out Mr. Blass's letter to my brother, who is a freezing engineer, and he showed me a copy of the *Zeitschrift für die Gesammelte Kälte-Industrie* (Munich) for August, in which an account is given of a machine on exactly the principle Mr. Blass suggests, by which Herr Linde has succeeded in liquefying air. It would appear, therefore, that the "theoretical minimum of temperature produced at C" would be determined by the point of liquefaction of the gas employed: with a perfect unliquefiable gas it would, I suppose, theoretically, be absolute zero. EDWARD T. DIXON.

Cambridge, September 22.

THE NEW MINERAL GASES.

OUR knowledge of the spectra and other conditionings of the new mineral gases has received an important addition in the communication from Drs. Runge and Paschen which appeared in last week's NATURE. The employment of exposures extending over seven hours has given a considerable extension in the number of lines, and the bolometer has been called in to investigate lines in the infra-red; better still, they have employed well-practised hands in searching for series of lines. Operating, by chemical means, upon a crystal of clèveite free from any other mineral, they have obtained a product so pure that from these series there are no outstanding lines. Very great weight, therefore, must be attached to their conclusions, and there are several points of contact with the work upon which I have been engaged from a slightly different stand-point since last April, when Prof. Ramsay made his fortunate discovery of a terrestrial source of helium.

I will touch upon some of these points *seriatim*.

In the first place, there has never been the slightest doubt in my mind that it was a question of gases and not of a gas. The spectroscopic evidence in the laboratory alone was complete, and the case was greatly strengthened when the behaviour of the various lines in the sun and stars was also brought into evidence. Drs. Runge and Paschen also declare that the gas given off even by a pure crystal of clèveite is not simple, but consists of two constituents. To the one containing the line D_3, which I discovered in 1868, the name helium remains; the other for the present, we may call "gas X." The chief lines of these two constituents are as follows, according to Runge and Paschen:

Helium.	Gas X.
5876	6678
4713	5048
4472	5016
4026	4922
3889	

Last May I wrote as follows[1]:—

"The preliminary reconnaissance suggests that the gas obtained from bröggerite, by my method, is one of complex origin.

"I now proceed to show that the same conclusion holds good for the gases obtained by Profs. Ramsay and Clève from clèveite.

"For this purpose, as the final measures of the lines of the gas as obtained from clèveite by Profs. Ramsay and Clève have not yet been published, I take those given by Crookes, and Clève, as observed by Thalén.

"The most definite and striking result so far obtained is that in the spectra of the minerals giving the yellow line I have so far examined, I have never once seen the lines recorded by Crookes and Thalén in the blue. This demonstrates that the gas obtained from certain specimens of clèveite by chemical methods is vastly different from that obtained by my method from certain specimens of bröggerite, and since from the point of view of the blue lines, the spectrum of the gas obtained from clèveite is more complex than that of bröggerite, the gas itself cannot be more simple.

"Even the blue lines themselves, instead of appearing

[1] *Proc.* Roy. Soc., vol. lviii. p. 114.

en bloc, vary enormously in the sun, the appearances being—

4922 (4921·3) = 30 times.
4713 (4712·5) = twice.

"These are not the only facts which can be adduced to suggest that the gas from clèveite is as complex as that from bröggerite, but while, on the one hand, the simple nature of the gases obtained by Profs. Ramsay and Clève, and by myself, must be given up, reasoning on spectroscopic lines, the observations I have already made on several minerals indicate that the gases composing the mixtures are by no means the only ones we may hope to obtain."

It will be seen that the laboratory separation of D_3 from the lines 5048, 5016, and 4922 was complete, and we now know that they belong to different series.

These lines have now been differentiated by Runge and Paschen by a different but equally satisfactory method.

Nor is this all. The difference between the results obtained by Thalén and myself seemed susceptible of explanation by admitting a fractional distillation, according to which D_3 and 447 came off first, and 4922, 5016, and 667 later on (Fig. 2).

Here also I got the same result as in the diffusion experiment referred to by Drs. Runge and Paschen. They found similarly—

Less bright.	More bright.
D_3	5016
	6678

All these various lines of evidence tend therefore to complexity, and there can be little doubt from the convergence of all these lines of work, the results of which agree among themselves, that we are in presence of at least two distinct gases, the complete spectra of which are those given by Drs. Runge and Paschen.

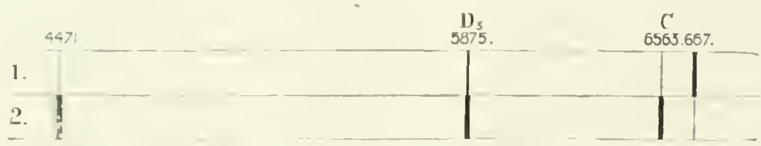

Fig. 1.—Diagram showing changes in intensities of lines brought about by varying the tension of the spark. (1) Without air-break. (2) With air-break.

Later on, in the same month, I returned to this subject, and showed that the lines at D_3 and 447 behaved in one way, and that at 667 behaved in another.

I wrote as follows[1]:—

"(1) In a simple gas like hydrogen, when the tension of the electric current given by an induction coil is increased, by inserting first a jar, and then an air-break into the circuit, the effect is to increase the brilliancy and the breadth of all the lines, the brilliancy and breadth being greatest when the longest air-break is used.

"(2) Contrariwise, when we are dealing with a known compound gas; at the lowest tension we may get the complete spectrum of the compound without any trace of its constituents, and we may then, by increasing the tension, gradually bring in the lines of the constituents, until, when complete dissociation is finally reached, the spectrum of the compound itself disappears.

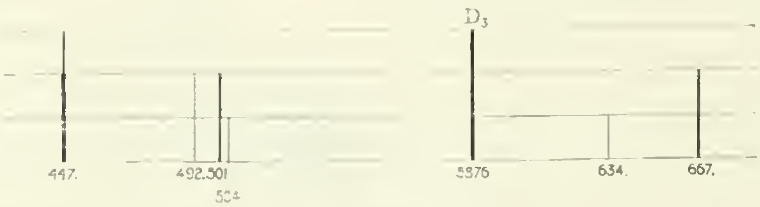

Fig. 2.—Diagram showing the order in which the lines appear in spectrum when bröggerite is heated.

"Working on these lines, the spectrum of the spark at atmospheric pressure, passing through the gas, or gases, distilled from broggerite, has been studied with reference to the special lines C (hydrogen), D_3, 667, and 447.

"The first result is that all the lines do not vary equally, as they should do if we were dealing with a simple gas.

"The second result is that at the lowest tension 667 is relatively more brilliant than the other lines; on increasing the tension, C and D_3 considerably increase their brilliancy, 667 relatively and absolutely becoming more feeble, while 447, seen easily as a narrow line at low tension, is almost broadened out into invisibility as the tension is increased in some of the tubes, or is greatly brightened as well as broadened in others (Fig. 1).

[1] Proc. Roy. Soc., vol. lviii. p. [illegible]

The second point is that there is no connection whatever between either of these gases and argon. Argon is of the earth, earthy, but helium and gas X are distinctly celestial, even more celestial than I thought when I claimed for them last May[1] the dignity of "a new order of gases of the highest importance to celestial chemistry." It was supposed at first that the spectra contained any number of common lines, next that there were two coincidences in the red between the new gases and argon; one I found broke down with moderate dispersion, the other has yielded to the still greater dispersion employed by Drs. Runge and Paschen; and, more than this, I have not found a single coincidence between argon and any line in the spectrum of any celestial body whatever. This happens, as everybody knows, also in the case of oxygen, nitrogen, chlorine, and the like.

The third point is as follows. So far I have worked upon some eighty minerals, and I have found the yellow line in sixteen; among the lines which I have already reported to the Royal Society are included all the stronger ones in the various series determined by the German physicists, but I can now add that in the region over which my work has extended, there is scarcely a single line in their series which I have not either seen or photographed in the spectrum of some celestial body or another. The following tables will show the results I have already obtained with all the six series of lines indicated by Drs. Runge and Paschen.

* Means that these lines are out of the range of my observations.

In the tables, under "Sun," C, followed by a number, indicates the frequency as given by Young; E indicates the lines photographed during the eclipse of 1893. Under "star or nebula" the references are to the tables given in my memoir on the nebula of Orion (*Phil. Trans.* vol. clxxxvi. (1895), p. 86 *et seq.* N = Nebula of Orion).

Hydrogen, helium, and gas X are thus proved to be those elements which are, we may say, completely represented in the hottest stars and in the hottest part of the sun that we can get at. Here then, in 1895, we have abundant confirmation of the views I put forward in 1868 as to the close connection between helium and hydrogen.

J. NORMAN LOCKYER.

RESEARCH IN ZOOLOGY AT OXFORD.[1]

THE second volume of the Linacre Reports, which has lately been printed, shows that the zoological laboratory at Oxford continues to be a source of production of many interesting and valuable contributions to knowledge.

In the course of a little more than one year the colleagues and pupils of Prof. Lankester have published a number of memoirs and essays, which, when collected together, form a bulky octavo volume, illustrated by numerous lithographs and woodcuts.

There is, as might be expected, considerable range in the interest and importance of the several items composing the volume, but not one of them could have been omitted without lessening its value to the zoologist. At least four of the memoirs are of such importance that they may be considered to be standard works to which reference must be frequently made in future by naturalists of all nationalities. Of these, perhaps, the most important is Prof. Poulton's memoir on the structure of the hair and bill of the duck-billed Platypus, which contains not only an excellent account of certain histological features of this rare animal, but some extremely suggestive remarks, derived from this research, on the relations of hairs and scales.

Dr. Benham's beautifully illustrated essay on the brain of the interesting Chimpanzee "Sally," which recently lived and died in the Zoological Gardens in London, forms an important chapter in "Man's place in Nature." The careful comparison which Dr. Benham gives of the large and valuable series of anthropoid and human brains which he has examined, makes this memoir one of special interest and importance.

Mr. Bourne's monograph on the post-embryonic development of Fungia gives us, at last, detailed information and good illustrations of a subject which has long interested zoologists.

The description of Prof. Lankester's collection of the species of Amphioxus and the genera allied to it, which has been carefully and ably written by Miss Kirkaldy, forms a memoir which will be welcomed heartily by zoologists in all civilised countries.

The other contributions to this volume are of less importance, perhaps, than those referred to above, but they are all useful additions to our knowledge of many widely separated branches of zoology, and being carefully written, and the result of work done under excellent advice and guidance, cannot be neglected by those who are specially interested in the branches of zoology of which they treat.

With such a volume of good useful work before us, it is truly lamentable to read in Prof. Lankester's editorial preface of the general indifference prevailing in the governing bodies of the Oxford colleges towards the progress of natural knowledge. The University of Oxford and the colleges together are the possessors of very large endowments for the cultivation of learning in all its branches. No university in the empire is so fortunately

[1] "The Linacre Reports." Vol. ii.

situated, as regards funds, as Oxford is at the present day, and yet the just claims of the most progressive sciences upon her vast resources are persistently neglected, and she remains in the position of a follower rather than a leader in most of the scientific movements of the day.

The efforts that Prof. Lankester has so successfully made to stimulate his pupils to investigate natural things, have been made in spite of, and not as they should have been with the warm support and sympathy of the collegiate systems that prevail in Oxford.

During the past ten years only four fellowships have been awarded to young zoologists of promise by the Oxford colleges. The recipients of this support have each produced valuable work, which has reflected great credit upon themselves and the enlightened action of the colleges to which they belong. Not one of them has joined the ranks of the idle fellows which abound in the old universities of this country. The experiment cannot, therefore, be said to be a failure. It is as a fact the most conspicuous success of any of the college enterprises of the present day. Why then, it may be asked, have not other colleges followed the example that has been set? The answer to this question is to be found in the fact that, in consequence of the unfortunate competition that exists between colleges to swell the ranks of their undergraduates, the income of the endowments is frittered away in the salaries of the heads, the stewards, the bursars, and the tutors of the pass-men. Whether the time will soon come when a radical alteration will be made in the administration of the college endowments it is difficult to say, but there can be no doubt that the present state of affairs as regards the support of natural science in Oxford is little short of scandalous, and should call for the serious attention of men of influence who have her interests at heart.

Prof. Lankester is to be congratulated on the efforts he has personally made, as shown by the two volumes of "The Linacre Reports," to stimulate research in his own branch of science at Oxford; and it is to be most sincerely hoped that, in a little while, his enterprise will meet with the recognition from the colleges that it deserves.

SYDNEY J. HICKSON.

DEEP SOUNDING IN THE PACIFIC.

A DEEPER spot in the ocean than any yet known has been recently found by H.M. surveying ship *Penguin*. Unfortunately the observation was not complete, as a fault in the wire caused it to break when 4900 fathoms had run out without bottom having been reached.

Commander Balfour reports that this occurred in lat. 23° 40' S., long. 175° 10' W., about 60 miles north of a sounding of 4428 fathoms obtained by Captain Aldrich in 1888. A previous attempt to reach bottom had been foiled by a similar accident to the wire when 4300 fathoms had passed out, and the rising wind and sea prevented any further attempt at the time. As the deepest cast hitherto obtained is one of 4655 fathoms near Japan, it is at any rate certain that the depth at the position named is at least 245 fathoms greater.

It is hoped that before long a more successful attempt to find the actual depth will be made.

September 28. W. J. L. WHARTON.

LOUIS PASTEUR.

ON Saturday afternoon, M. Pasteur died at Garches, near St. Cloud, where he had gone for the summer in order to be near Paris, and at the same time to be near the large establishment for the preparation of antitoxic serum.

In 1868, Pasteur suffered from an attack of paralysis, the result apparently of a cerebral hæmorrhage; but although traces of this paralysis remained, he enjoyed fairly good health until 1887, when he developed symptoms of heart and kidney disease, probably a recrudescence of the diseases associated with his earlier paralysis. Four years ago he suffered from influenza, which appears to have left further weakness of the heart. Last winter he was unable to do any work, and in fact was confined to bed for several months; but when summer came, he was able to go to his country house at Villeneuve l'Etang, near St. Cloud, where he remained in comparatively good health, though easily fatigued, until about three weeks ago, when he seems to have felt that the end was approaching. It is stated that "about three weeks ago he kissed his grandchildren fondly, and pressed each for some time to his breast, sobbing as he did so. On being asked what was the matter, he said 'The matter is that I must so soon leave them.'" He appeared to be no worse at this time, but about a week later symptoms of uræmia began to develop, he became comatose, and on Wednesday last the uræmic poisoning became more marked, and by Friday it was evident that there could be only one termination to the illness.

In 1891 (NATURE, March 26) we gave a sketch of his life from the pen of Sir James Paget, some features of which may now be repeated. "Louis Pasteur was born on December 27, 1822, at Dôle, in the Jura, where his father, an old soldier who had been decorated on the field of battle, worked hard as a tanner." Father and mother alike seem to have been earnest, thoughtful people, whose one ambition seems to have been to "make a man" of their son.

"In 1825 they removed to Arbois, and as soon as he was old enough to be admitted as a day boy, Pasteur began his studies in the Communal College, and there, after the first year or two, he worked hard and gained distinction." He then, in turn, studied for a year at the college of Besançon and at the École Normale. He was only fourteen when he first applied for admission, but it was not until he had studied for a year that he went in for the examination; and in 1843 it is recorded that he was fourth on the list of successful competitors. At a very early period he devoted special attention to chemistry under Darlay at Besançon, and then under Dumas at the Sorbonne, and Balard at the École Normale. Here, too, in the École Normale, he commenced that study of molecular physics, especially in relation to the formation of crystals, which led up to his now classical investigation on the isomeric crystals of the tartrates and paratartrates of soda and ammonia. In 1847 he took his degree of Doctor of Science, after which he was appointed Assistant and then Professor of Chemical Physics in the University of Strassburg. In 1854 he was appointed Dean of the Faculty of Sciences at Lille, where he spent three years in organising the new school, and commenced those experiments on fermentation which seemed to follow naturally on his researches on the tartaric acids. He found that certain processes of fermentation were set up by distinct micro-organisms, under the action of which organic salts and even inorganic substances were broken down, and others were formed in their place. Three years later he was appointed Director of Studies in the École Normale in Paris, which office he retained until 1867. During this same period he was Professor, first of Geology, then of Physics, and latterly of Chemistry in the École des Beaux Arts. He also held the position of Professor of Chemistry at the Sorbonne.

As early as 1856, before his recall to Paris, the Royal Society of London awarded to him the Rumford Medal for his researches on the polarisation of light. In 1869 he was made a foreign member of the Royal Society, and in 1874 the Copley Medal was given to him. It is interesting to note in connection with his recent action as regards the Order offered to him by the Emperor William, that, during the bitterness caused by

the war, M. Pasteur sent back the Diploma of Doctor given to him by the University of Bonn in 1868, and subsequently received a message from the students calling him an impostor and a quack. In 1881 Pasteur was elected a member of the French Academy, succeeding to the seat of M. Littré. About the same time he was made an honorary Doctor of Science of the University of Oxford. In 1887 he was appointed perpetual secretary of the Academy of Sciences, but in 1889, owing to the failure of his health, he was compelled to hand over the duties of this position to M. Bertholet.

At the conclusion of his researches on crystals and wine fermentation, Pasteur commenced an inquiry into the diseases of the silkworm, and in no investigation that he undertook were his method and thoroughness more fully exemplified than in this. When he commenced his inquiry he had never even seen a silkworm, but for four years he spent several months of each year in tracing the germs of the "pebrine" disease through the various stages of development of the worm, egg, larva, chrysalis, and moth. He found what he described as "corpuscles," which he indicated were the contagious elements of the disease. These were taken up from the mulberry-leaves on which they had been previously deposited by diseased moths: some of the worms died, but others went on to the chrysalis and even to the moth stage, still affected by these "corpuscles," and the eggs laid by these moths were also found to contain them. He was convinced that the only way was to breed from moths not affected by the disease, and "to this end he invented the plan which has been universally adopted, and has restored a source of wealth to the silk districts: each female moth, when ready to lay eggs, is placed on a separate piece of linen, on which it may lay them all; after it has laid them and has died, it is dried, and then pounded in water, and, the water is then examined microscopically. If "corpuscles" are found in it, the whole of the eggs of this moth, and the linen on which they are laid, are burnt; if no corpuscles are found, the eggs are kept, to be, in due time, hatched, and yield healthy silkworms."

Pasteur's experiments on fermentation began to have a more direct bearing on disease when Sir Joseph Lister, applying the principles to the changes that occur in wounds, was able by his antiseptic practice to exclude putrefactive and septic germs from wounds, and so to prevent those terrible sequelæ which were the terror of surgeons of the past generation.

Then came Pasteur's great work in bacteriology, his attenuation of the anthrax bacillus and of other pathogenic organisms by which he procured a vaccinating virus, capable of producing a mild form of the disease: as a result of this attack vaccinated animals were protected against the attacks of the non-attenuated organism. This was first proved in connection with fowl-cholera, then in connection with swine erysipelas; but the most important application at that time was in connection with anthrax. His work on hydrophobia is still fresh in the minds of all. Pasteur's work does not end with his death. He had collected in the Institut Pasteur, which was raised as a memorial to his life's work, a band of able and well-trained investigators, who are imbued with the spirit that animated his mind and soul—men who, under his advice and encouragement, are working out the details of the great works that he initiated, who are endowed with some of his great mental power, and who have been fully trained under his eye in the methods of direct experiment and accurate observation, men who have been taught by him "n'avancez rien qui ne puisse être prouvé d'une façon simple et décisive," a rule always practised by himself.

France may well offer a public funeral. Louis Pasteur was one of her noblest sons—an honoured one during his life, and deeply lamented now that he is dead.

In Pasteur not only has France lost the greatest Frenchman, but the world has lost one of its greatest benefactors, not only of this age but of all time. Letters and telegrams of condolence have been sent by men of light and leading in many nations, and they indicate the sorrow felt unto the ends of the earth. No greater testimony than this could be given of the esteem in which the memory of the great investigator is held. The blessings which the human race owes to Pasteur have been recognised for some time, and now that the mind which gave them birth is at rest, one great outburst of grief arises. The expression of sorrow in France is full and sincere. At the funeral, which is arranged to take place next Saturday, the President of the Republic will be present, and other representatives of the French Government, together with a multitude of fellow-workers and friends who revere Pasteur's memory. The funeral procession will first proceed to Notre Dame, where a solemn requiem will be chanted in presence of the Archbishop of Paris. The body will afterwards be placed in one of the vaults of the cathedral until the celebration of the Centenary of the Institute of France, in three weeks' time, when it will be removed to its final resting-place. It has been arranged that the body of the great investigator shall be finally interred at the Institute which bears his name, and which will form a fitting monument to him. The representatives of science who will be assembled in Paris for the Centenary will accompany the transfer of the mortal remains of their foremost fellow-worker: so that while they unite to celebrate the foundation of the Institute of France, they will join together in sorrow for the deep loss which science has sustained.

NOTES.

THE eleventh International Geodetic Conference was opened at Berlin on Tuesday. Representatives were present from Austria, Belgium, France, Italy, Japan, Norway, Servia, Spain, Sweden, Switzerland, and the United States. The proceedings were opened by Dr. Bosse, the Prussian Minister of Public Education.

A NEW meteorological observatory is reported to have been opened on the Brocken, in the Harz Mountains, on Tuesday. The observations obtained there will be useful for discussion in connection with those made at the observatory on Ben Nevis.

SIR DAVID SALOMONS has arranged for an exhibition of horseless carriages on Tuesday, October 15, at the Tunbridge Wells Agricultural Show Ground, which has been lent to him for the occasion. The carriages will enter the ring at three o'clock p.m. The entrance money received will be used for prizes to be awarded at the show of the Tunbridge Wells and South Eastern Counties Agricultural Society next year, for the best horseless carriages intended to be used for agricultural, trade, and private purposes. Invitation tickets for the exhibition may be secured in order of application by Fellows and Members of the following Institutions sending an addressed envelope to one of the Secretaries—the Institution of Civil Engineers, the Institute of Electrical Engineers, the Institute of Mechanical Engineers, the Royal College of Physicians, and the Royal College of Surgeons.

THE Medical Schools attached to London and provincial hospitals commenced a new session on Tuesday with the customary introductory addresses. Prof. J. R. Bradford, at University College, discussed the positions occupied by biology, anatomy, and physiology in the medical curriculum. Dr. A. P. Laurie addressed the students at St. Mary's Hospital on the medical profession and unhealthy trades. At the London Hospital, Dr. J. Hughlings-Jackson was presented with his portrait and a piece of plate, in recognition of his great services to the London Hospital and Medical College, of his distinguished position in the profession, and of the advance he has effected in medical science by his laborious investigations and profound

insight into the diseases of the nervous system. The presentation was made by Sir James Paget, who also presented the prizes to the students. Mr. G. D. Pollock advised the students at St. George's Hospital as to their methods and aims of work. A valuable address on the more important developments of modern medicine, especially in the department of bacteriology, was given at Westminster Hospital by Dr. S. M. Copeman. Dr. W. J. Mickle discoursed on psychological medicine at Middlesex Hospital, and Dr. G. D'Ath read a paper at Guy's Hospital on "Our Profession, our Patients, our Public, and our Press." The introductory address to the students of the London School of Medicine for Women was given by Miss Ellaby.

The annual exhibition of natural scientific specimens of the South London Natural History Society will be held at the St. Martin's Town Hall, Charing Cross, on the evening of October 17.

A portrait bust in bronze of the late Dr. Robert Brown, the botanist, has been presented to the Montrose Town Council by Miss Paton, a kinswoman of the botanist; it has been placed in a niche in the house where Dr. Brown was born in 1773.

The *Lancet* announces that a subscription has been opened in Bristol to provide for the purchase and retention in that city of the celebrated collection of relics belonging to Jenner in connection with his introduction of vaccination. The collection is at present the property of Mr. Frederick Nockler, of Wotton-under-Edge, and was exhibited by him at the Bristol Exhibition in 1893, and since then in London, at each of which places it attracted a considerable amount of attention.

Was any record obtained of an earthquake in England on September 13? A correspondent informs us that at 12.25 a.m. on that day, four slight but very distinct shocks were felt two miles north-west of Southampton. The shocks caused the room to shake, and a deep grinding noise was heard; they occurred a few seconds after each other, but the interval between the third and fourth was a little longer than that between the previous tremors. The last shock appears to have been the most intense.

On Saturday, September 14, the ceremony of breaking the soil preparatory to the erection of the new building of the Brooklyn Institute, was performed in that city. The estimated cost of the new building is several millions of dollars, as its projectors intend it to be one of the finest and most complete of its kind erected. The Institute, which has a membership approaching 4000, has never yet had a suitable home, and it is confidently anticipated that rapid strides in membership and usefulness will be made when the present scheme has been carried to a conclusion.

We much regret to have to record the death, from injuries received whilst riding his bicycle, of Prof. C. V. Riley, of Washington. Prof. Riley, who was fifty-two years old and a native of England, died on September 14. He was for many years State entomologist of Missouri, and from 1878 till 1894 was Government entomologist of the United States, and as such did very much in devising and applying means to destroy noxious insects. His successful experiment in checking the ravages of the white scale in California, a few years ago, by introducing the parasitic lady bug, *Vedalia cardinalis*, was among the most brilliant triumphs of economic entomology. Prof. Riley has written and published much. He was one of the original Fellows of the American Association for the Advancement of Science, and President of the Zoological Section in 1888, when he delivered an address on the causes of variation in organic forms.

Authorities have differed much as to the character of crystallised bromine. Gmelin-Kraut's Hand-book describes the solid substance as steel grey and similar to iodine, whereas Schutzenberger says "solid bromine is a crystalline, brown-red mass, and not grey-blue, as it is often described." The *Zeitschrift für Anorganische Chemie* (x. 1 and 2) gives a short account of its preparation by Henryk Arctowski by a new method. A very concentrated solution of bromine in carbon bisulphide, when cooled to $-90°$, deposits the halogen in the crystalline form and free from the solvent. When thus obtained, bromine forms a mass of fine needles of some millimetres length, which have a fine dark carmine-red colour like that of chromium trioxide. Solid bromine, obtained in mass, has a crystalline fracture, and has no well-defined metallic lustre like iodine; at the best, it has a dull black metallic appearance.

The boiling point and the critical temperature of hydrogen, concerning which Prof. K. Olszewski made a preliminary statement in Nature some little time ago, have since been determined by him with every precaution against error, with the result that his first estimate is proved to have been very near the truth. In the current number of *Wiedemann's Annalen* the process is described in detail. The "expansion method," which had already been successfully employed to determine the critical pressure, was again utilised, the critical temperature being the temperature at which liquid hydrogen, when slowly released from pressure, first boils up, and the boiling point being the temperature attained when the pressure is reduced to that of one atmosphere. The chief difficulty was, as usual, that of determining the temperature accurately. Prof. Olszewski succeeded here by using a coil of thin platinum wire immersed in the hydrogen, whose varying resistance indicated the amount by which it was cooled. This coil was placed in a cast-iron cylinder into which hydrogen was conducted from a reservoir under 180 atmospheres pressure. The cast-iron cylinder could be brought down to a temperature of $-210°$ C., not far from the absolute zero, by means of liquid oxygen. But the critical temperature of hydrogen was found to be still lower, viz. $-234·5°$ C., and had to be found by extrapolation. The boiling point was $-243·5°$ C., or $-406·3°$ F.

In a report on the Coosa coal-field, published by the Geological Survey of Alabama, Mr. A. M. Gibson describes some remarkable effects of the great "cloud-bursts" which devastated that region in 1872, and are still conspicuous after a lapse of over twenty years. Clean-cut channels, in one case sixty feet wide and three or four feet deep, are described as extending down the mountain sides. They were formed by the direct force of the downpour of water, and along them were carried great masses of rock—one weighing a hundred tons—earth, trees, &c., which formed moraine-like masses at the base, or were scattered far over the lower ground.

Vol. vi. of the new series of Reports of the Geological Survey of Canada has recently been published, and contains the annual reports for the years 1892 and 1893, two special preliminary reports on particular districts (namely, parts of Ontario and Nova Scotia), and chemical and mining reports illustrated by numerous statistical diagrams. Among the matters of general interest, we may note the results of Mr. Low's exploration of Labrador. He finds that the interior of Labrador is well-wooded, instead of being a treeless wilderness as generally supposed, and finds evidence that the continental ice-cap took its rise in the interior of that country. In the chemical report, Mr. G. C. Hoffmann records a remarkable mineralogical discovery. In the kaolinized perthite from a pegmatite vein are found spherules of metallic iron, mostly minute but at times measuring as much as a millimetre in diameter, and having a siliceous nucleus. Mr. Hoffmann refers to similar spherules described by him some years ago (*Trans. Roy. Soc. Canada*, vol. viii. sec. iii. p. 39), on the joint-surfaces of a quartzite, and considers that the explanation suggested in that case applies here again—that the iron has been reduced from limonite by the action of organic matter.

THE Canadian Geological Survey has published the second part of vol. iii. of its monographs on "Palæozoic Fossils," in which Mr. Whiteaves describes and figures fossils—chiefly Gastropods and Brachiopods—from the Guelph and Hudson River formations.

WE have received from Mr. J. H. Knowles, of Lavender Hill, S.W., a catalogue of various books of science which he has for sale. Many interesting and valuable works on Ornithology, Botany, Astronomy, and other sciences are included.

MESSRS. JARROLD AND SONS have just published an abridged edition of "The Official Guide to the Norwich Castle Museum," at the small price of sixpence. The chief author of the book is Mr. T. Southwell, who has produced a work that should be in the hands of all visitors to the museum, which it so well describes. The little work is admirably compiled, and is illustrated by numerous figures in the text.

THE valuable series of reprints now being published by Mr. Engelmann, of Leipsig, under the title of Ostwald's "Klassiker der Exakten Wissenschaften" has recently had four more volumes added to it. These, numbered 63 to 66, contain respectively the following papers:—"Zur Entdeckung des Elektromagnetismus," by H. C. Oersted and T. J. Seebeck; "Über die Vierfach Periodischen Functionen Zweier Variabeln," by C. G. J. Jacobi; "Abhandlung ueber die Functionen Zweier Variabler mit vier Perioden," by G. Rosenhain; and "Die Anfänge des Natürlichen Systemes der Chemischen Elemente," by J. W. Doebereiner and Max Pettenkofer.

WE have received part i. vol. vi. of the *Transactions* of the Norfolk and Norwich Naturalists' Society, by which it appears that the Society has just completed its twenty-sixth year, and to be financially in a prosperous condition; now numbering 275 members, amongst whom we recognise many well-known names. The presidential address, by Dr. Plowright, was mainly devoted to the consideration of some obscure points in the life-history and development of the various forms of *Puccinia*, which he showed had by no means been worked out, and indicated the direction in which further investigations should be pursued. Amongst the papers read before the Society, and published in their *Transactions*, is a very interesting one on "Neolithic Man in Thetford District," with illustrations of the various types of flint implements found in the river-gravels of that neighbourhood. The usual "Report on the Herring Fishery of Yarmouth and Lowestoft" is also published, which having been continued for fourteen consecutive years, in the absence of trustworthy statistics on the subject elsewhere, should be possessed of value; and the same may be said of the very full meteorological notes by Mr. A. W. Preston. A chatty paper on "Old-time Yarmouth Naturalists," by Mr. F. Danby-Palmer, should also be mentioned as giving some particulars of the more noticeable of the old-time naturalists, for which that ornithologically rich section of the east coast has always been remarkable. There are fifteen published papers in all, each of which speaks well for the vitality and usefulness of the Society.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*, ♀ ♀) from India, presented respectively by Mr. Thomas Mackenzie and Messrs. Davies and Sons; a Chimpanzee (*Anthropopithecus troglodytes*, ♂) from West Africa, presented by Captain G. C. Denton; a Piping Guan (*Pipile cumanensis*) from Uruguay, presented by Mr. P. du Pré Grenfell; four Green Lizards (*Lacerta viridis*), three Wall Lizards (*Lacerta muralis*), European, presented by Mr. C. W. Tytheridge; two Laughing Kingfishers (*Dacelo gigantea*) from Australia, deposited; a Common Seal (*Phoca vitulina*) from Scotland, purchased.

OUR ASTRONOMICAL COLUMN.

RETURN OF FAYE'S COMET.—A telegram from Kiel, received on September 28, announces that Faye's comet was observed by Javelle at Nice on the 26th. At 12h. 34·8m., Nice time, it was in R.A. 21h. 8m. 11s., and Decl. 1° 54′ S. It is accordingly well situated in the north-western part of the constellation Aquarius, crossing the meridian a little before 9 p.m. At the time of observation it was noted as "feeble."

ELEMENTS AND EPHEMERIS OF COMET *a*, 1895 (SWIFT).—Dr. Berberich has computed the following new elements of Swift's comet, from observations made at Mount Hamilton, August 21; Nice, August 31; and Strassburg, September 16.

These elements represent the comet's orbit with a greater degree of accuracy than those previously deduced, and the ephemeris determined from them closely represents observations made at Paris. In continuation of the ephemeris given in NATURE of September 5, we print the following, from *Edinburgh Circular* No. 46:—

T = 1895, *Aug.* 20, 88480 *M. T. Berlin*

$$\left.\begin{aligned} \pi - \Omega &= 167^\circ\ 47'\ 7''\cdot8 \\ \Omega &= 170\ 16\ 17\cdot3 \\ i &= 2\ 59\ 24\cdot9 \end{aligned}\right\} 1895\cdot0 \qquad \begin{aligned} \mu &= 502''\cdot654 \\ \log a &= 0\cdot565825 \\ \log q &= 0\cdot112686 \end{aligned}$$

$$\phi = 40\ 22\ 17\cdot6 \qquad \text{Period} = 7\cdot059 \text{ years.}$$

Ephemeris for Berlin Midnight.

1895.		α app. h. m. s.		δ app. ° ′		Brightness.
Oct. 2	...	1 24 7	...	+4 32·9		
4	...	1 24 41	...	4 23·9	...	0·62
6	...	1 25 9	...	4 15·3		
8	...	1 25 31	...	+4 7·1	...	0·56
10	...	1 25 50	...	+3 59·5		
12	...	1 26 6	...	3 52·5	...	0·50
14	..	1 26 19	...	3 46·2		
16	...	1 26 31	...	3 40·6	...	0·44
18	...	1 26 42	...	3 35·8		
20	...	1 26 53	...	3 31·9	...	0·38
22	...	1 27 5	...	3 29·0		
24	...	1 27 19	...	3 27·0	...	0·33
26	...	1 27 35	...	3 25·9		
28	...	1 27 53	...	+3 25·7	...	0·29

It will be noticed that the comet is diminishing in brightness, and on October 12 will only be half the brightness at the time of discovery, August 20.

γ VIRGINIS.—Of the many double-star orbits which have recently been computed by Dr. See, of Chicago, none presents more features of interest than that of γ Virginis. This famous double star has been very persistently observed since its discovery in 1718, but none of the orbits previously determined are consistent with the most recent observations. Including some of his own measures, Dr. See finds the following elements (*Astronomical Journal*, No. 352):—

$$\begin{aligned} P &= 194\cdot0 \text{ years} & \ldots\quad \Omega &= 50\cdot4 \\ T &= 1836\cdot53\ \ ,, & \ldots\quad i &= 31\cdot0 \\ e &= 0\cdot8974\ \ ,, & \ldots\quad \lambda &= 270\cdot0 \\ a &= 3''\cdot989 & \ldots\quad n &= 1\cdot8557 \end{aligned}$$

Apparent orbit:

Length of major axis = 6″·824
,, ,, minor axis = 3″·530
Angle of major axis = 140°·4
,, ,, periastron = 140°·4
Distance of star from centre = 3″·062

A comparison of computed and observed places shows, according to Dr. See, that these elements are probably the most exact yet found for any binary star. It will be seen from the figures given that the line of nodes coincides with the minor axis of the real ellipse, which is also the minor axis of its projection; and, owing to the small inclination, the apparent ellipse is only slightly less eccentric than the real ellipse, so that the foci of the two ellipses nearly coincide. Dr. See points out that one of the consequences of this disposition of the orbit is to make the movement of the radius vector in the apparent orbit very little different from that in the real orbit, so that γ Virginis furnishes the best test we have for the exactness of the law of gravitation in stellar systems. "If there is any deviation from the Keplerian law of areas, it must be extremely slight. There-

re the force is nearly central, and if it differs at all from the law of Newton, the deviation must be relatively unimportant."

The orbit is also remarkable for its great eccentricity, which surpasses that of any known stellar orbit.

For many years to come the angular motion will be very slow, and Dr. See draws attention to the fact that observations of distance will be more valuable than angular measures in effecting further improvement in the elements.

THE THIRD INTERNATIONAL ZOOLOGICAL CONGRESS AT LEYDEN.

FROM first to last this Congress, the Session of which lasted from September 15 to 21, was favoured by exceptionally fine autumn weather, and the quaint old town of Leyden, where the meeting was held, as well as the island of Marken, the Zoological Park at Graveland (where apteryx thrives and gnus are kept in free pastures), the Zoological Station at Helder, the sea-beach of Katwijk and Scheveningen, and the port of Rotterdam, to all of which places excursions were organised, were under these circumstances seen at their very best.

The character of the meeting was eminently international. The daily bulletin, although edited in French, contained announcements of lectures to be held and of papers to be read in English and in German, and in the Sections these three different tongues often succeeded one another rapidly and fraternally.

On the Sunday evening preceding the official opening there had been an informal mustering of the forces then already assembled, and Prof. Hubrecht, of Utrecht, who, as President of the Netherlands Zoological Society, gave a hearty welcome to those present, hinted at the inadvisability of allowing the use of more than these three languages.

Still, besides forty-two representatives from Great Britain and the United States, sixty-three from France and Belgium, and twenty from Germany and Austria, there were no less than eleven Russians, eight Scandinavians, and sixty-four Dutchmen inscribed as members, who had to restrict the use of their native language to conversation among themselves.

The total number of members inscribed was 232, and not only the number but also the quality of the zoologists assembled was such as to make this international gathering really a very representative one, which served to bring together some of the veterans of the old guard, and a great number of the younger generation of zoologists.

A glance along the list of those that were present will show this at once. There we find Jul. Vict. Carus, Th. Eimer, V. Hensen, A. Metzger, F. E. Schulze, R. Semon, J. W. Spengel, R. Virchow, Aug. Weismann, K. Grobben, Ch. Julin, E. de Selys Longchamps, C. Lutken, H. Field, O. C. Marsh, W. B. Scott, C. W. Stiles, R. Blanchard, E. Bouvier, A. Certes, A. Milne-Edwards, E. Perrier, L. Vaillant, J. Anderson, Sir W. H. Flower, S. J. Hickson, John Murray, Adam Sedgwick, R. B. Sharpe, R. Trimen, d'Arcy Thompson, S. Apathy, S. Brusina, C. Emery, R. Collett, A. Kowalevsky, W. Schimkevitch, W. Salensky, W. Blasius, N. Zograff, W. Leche, F. A. Smitt, Th. Studer, van Wyhe, Max Weber, Vosmaer, Sluiter, van Lees, Lidth de Jeude, Kerbert Jentink, Hubrecht, Hoffmann, Hoek, Horst, Everts, Büttikofer, M. C. Dekhuyzen, E. Rosenberg, and van Bemmelen. Very many of these read papers in the Sections, three of them (John Murray, A. Milne-Edwards and Weismann) addressed general meetings; whereas on the Tuesday evening a lecture on the curiosities of bird life, illustrated by coloured lantern-slides, was given by Dr. Bowdler Sharpe, of the British Museum, and was attended by the young Queen and the Queen-Regent.

The Committee of Organisation, to whose excellent arrangements much of the success of the meeting was due, were Prof. Hubrecht of Utrecht, Dr. Jentink, Director of the Natural History Museum, Leyden (President of the Congress), Dr. Hoek (Secretary), and Dr. Horst (Treasurer).

There were six different Sections, a new feature of which was the inclusion of palæontology with recent zoology. There was no separate Palæontological Section.

In the first Section (general zoology, geographical distribution, with the inclusion of fossil faunas and evolution theory), Mr. A. Sedgwick, of Cambridge, gave an exposition of his views concerning direct cellular continuity in the living organism. In a later meeting of the same Section, Prof. Apathy, of Klausenburg (Hungary), demonstrated a series of the most beautiful and delicate microscopical preparations, which, already at an earlier date, have led him to conclusions very similar to those of Sedgwick just referred to.

Prof. Hensen, of Kiel, gave an interesting account of the Plankton expedition, its aims and its results.

Prof. Eimer, of Tubingen, spoke in this Section on the subject of orthogenesis, and on the impotence of natural selection for the production of new species.

In the second and third Sections, devoted to living and extinct vertebrates, their anatomy and embryology, papers were read by Profs. Zograff of Moscow, Vaillant, O. C. Marsh, Büttikofer, Lutken, Leche, Semon, Hubrecht, and van Bemmelen.

The fourth, fifth and sixth Sections embraced the invertebrates, one of them being specially devoted to entomology. Messrs. Wardell Stiles (from the United States), Hickson, Blanchard, Goto (from Tokyo), Perrier, Kowalevsky, Schimkevitch, Gilson, Salensky, and Julin were among the principal speakers in these Sections.

The sectional meeting which proved to be the most attractive was the one that was held on the last day of the meeting, when in the second Section, temporarily presided over by Rudolf Virchow, Dr. E. Dubois, the indefatigable naturalist, who has devoted the last six years to the collection of palæontological specimens in Sumatra and Java, gave a full account of the finding of the remnants of his *Pithecanthropus erectus*.

The four fragments (a femur, the upper part of a skull, and two teeth) upon which this new species, looked upon by its author as an intermediate stage between the anthropoids and man, was founded, were laid before the Section, together with a good many pieces intended for comparison. A most interesting discussion followed, in which Virchow, O. C. Marsh, Emil Rosenberg, Sir William Flower and Prof. Martin took a prominent part. Virchow's contention was that the four fragments did not belong to the same animal. He attempted to derive arguments from pathological anatomy, which would show that the osteophytic outgrowths of the femur described by Dubois were indications tending rather towards the human than towards the simian origin of the femur. Nevertheless, he spoke in a very appreciative tone, telling the Section that he had only wished to put in a point of interrogation where Dubois' affirmations did not appear to him to be as yet fully justified.

Prof. Marsh was inclined, on grounds derived from his vast experience in palæontological excavations, to support many of Dubois' conclusions. He had noticed exostoses of a similar nature as those of Pithecanthropus in fossil animals of quite different orders. He pointed out the necessity of carefully comparing these remains with those from the Sivalik Hills.

Prof. Rosenberg, considering more especially the femur and the cranium from the point of view of the anatomist, tried to show that the four characteristics, by which Dubois separates the femur of Pithecanthropus from that of man, are found also in human femora, in some few cases even all of them combined. The skull, on the contrary, is more that of a primate; but he did not agree with Dubois' argument that certain peculiarities of its *planum nuchale* tended to show that the animal had assumed a more erect gait. Very similar peculiarities are found in the New-World Cebus, which moves on all fours. Rosenberg acknowledged, however, that the high intrinsic value of the fragments was in no way diminished by the doubts expressed by him, because the femur, even if human, would prove Tertiary man to have existed in Java, the origin of man being thus pushed further back towards the earlier Tertiary period.

The results of this discussion, though not a decisive triumph for Pithecanthropus as a valid species, was a unanimous recognition of the great importance of Dr. Dubois' researches.

Another interesting afternoon lecture, which attracted numerous members of different Sections, was given by Prof. W. B. Scott, of Princeton, and was illustrated by lantern-slides. The wonderful continuity of the American tertiary formations, the vast geographical scale on which they are developed, and the excellent state of preservation of their fossils, was specially insisted upon. Skeletons of many members of the beautifully continuous phylogenetic series were projected on the screen.

Of the lectures held at the general meetings, those of Dr. John Murray and Prof. Milne-Edwards were most interesting to the audiences they addressed. Prof. Milne-Edwards spoke on the extinct avifauna of the Mascarene Islands in its relation to that of certain islands in the Pacific Ocean, and Dr. Murray gave an admirable survey of deep-sea exploration in general,

and of its principal results. In seconding a vote of thanks to Dr. Murray, Prof. Milne-Edwards availed himself of the opportunity of complimenting him, in terms of the highest eulogy, on the completion of the *Challenger* Reports, the cost of which has been so liberally met by the British Government, and the editorship of which has been in the hands of Dr. Murray since the death of the late Sir Wyville Thomson.

Prof. Weismann's lecture to the general meeting treated of a much more abstruse and complicated subject, viz. Germinal Selection. Under this name he introduced what he holds to be a supplementary hypothesis to that of Natural Selection, and by which he explains the fact that useful variations appear to be protected from their very first appearance, so that, when natural selection would require them, they are indeed always there. The simultaneous development of harmonious variations of different parts of the same organism was at the same time elucidated on similar principles.

It may be noticed in passing, that these theoretical views of Weismann's approach very closely to views expressed as the result of quite different series of palæontological observations by W. B. Scott and others. It is clear that an explanation of certain groups of facts is yet wanted. Weismann will have to show that his speculations do indeed bridge this gap.

In the three general meetings other questions of international significance were settled. In the first one, presided over by the Minister of the Interior, Mr. van Houten, the prize to which the name of the present Emperor of Russia is attached was awarded to Dr. R. T. Scharff, of Dublin. In the second one, of Wednesday, September 19, the conclusions of a report of M. Bouvier, on the question of bibliographical reform, were unanimously carried, and seven members of the Controlling Commission nominated, viz. Messrs. Spengel, Sidney Hickson, W. B. Scott, Blanchard, Hoek, Schimkevitch, and Lang.

Another commission for the definite codification of the rules of zoological nomenclature was appointed, and consists of Messrs. Blanchard, Victor Carus, Jentink, Sclater, and Wardell Stiles.

In the final meeting, Sir William Flower was nominated to the presidency of the next Zoological Congress, in 1898. Upon the proposition of the President of the Congress, in the name of the Committee of Organisation, it was decided to meet in England, the exact place of meeting being left to the consideration of the permanent Bureau.

During the Congress, as has already been announced in NATURE, three of its most eminent members—Messrs. Weismann, Milne-Edwards, and Sir Wm. Flower—received the honorary degree of Doctor in Science (Section of Zoology and Botany) from the Senate of the Utrecht University, upon the proposal of the Faculty of Natural Philosophy.

On Saturday the meeting closed, and the members united in a farewell banquet in the concert hall, where the Minister of the Interior was again present.

On Sunday, the 22nd, the Amsterdam Zoological Society *Natura Artis Magistra* invited the members to a luncheon party, and to a visit to its well-known gardens and aquarium.

After this the members of the Congress definitely separated. There is not one of them who has not extended the circle of his personal acquaintance amongst his fellow-workers in the field of zoology. And this extension of the feelings of international scientific fraternity is one of the great advantages of these cosmopolitan gatherings.

THE INTERNATIONAL CONGRESS OF PHYSIOLOGISTS AT BERN.

I.

MONDAY, September 9.—Presidents, Profs. Chauveau and Bowditch. Dr. Boruttau (Göttingen) demonstrated on a platinum wire contained in a glass tube filled with ·6 per cent. salt solution, electrical changes (negative variation), analogous to those occurring upon stimulation of a nerve trunk. The negative variation occurred not only upon electrical, but also upon chemical and mechanical stimulation of the wire. The apparatus used for the purpose were a Hermann's repeating rheotome and a Thomson's galvanometer.

Profs. Ewald and Goltz (Strassburg) showed a dog from which they had removed, at three successive stages, large portions of the spinal cord. In all 158 mm. had been removed: this involved all the spinal cord below the middle dorsal region, inclusive of the cauda equina. The dog had already survived the last operation two years. The condition was as follows:—(1) Entire muscular degeneration of hind limbs, and back muscles below mid-dorsal region; (2) evacuation of fæces, and sphincter ani ext., normal; (3) large quantities of urine collected in bladder, but were eventually evacuated; (4) vascular tone normal. Animal gave birth to young ones since last operation, and suckled them normally.

Prof. Fano (Florence) showed a special apparatus by which he could measure exactly motor reaction time. He worked on the dog, and found that it was 32·6 sec. for anterior paw, 27·32 for posterior. After removal of parts of cortical layer of frontal and occipital lobes this reaction time was diminished; upon stimulation of same regions it was increased. From this the author concluded that the cortical cells, especially of the frontal region, exert a constant inhibitory action on the spinal cord.

Prof. Langley (Cambridge) gave a demonstration on (1) the general anatomical relations of the sympathetic system; (2) connection of nerve cells and nerve fibres; (3) reflexes from the sympathetic system.

Dr. Mann (Edinburgh) read a paper, accompanied by lantern-slides, and gave a demonstration on the position of the psycho-motor areas in the rabbit, hedgehog, dog, and cat. The result of the author's researches was to show that (1) the same general scheme of arrangement of the psycho-motor areas holds good throughout the animal kingdom, and (2) that there exist in the above animals centres of varying psycho-motor value (higher and lower centres in the physiological sense).

Prof. Gaule (Zürich) discussed the growth of muscle, and came to the conclusion that it was periodic, and that there exist in muscular fibres changes corresponding to these periods. He further discussed and showed the effect of excision of the inferior cervical ganglion upon the biceps and psoas of the same side. Within twenty-four hours of this excision these muscles increase in weight, and have their resistance to mechanical strain greatly diminished (rupture easily).

Prof. Vitzou (Bucharest) produced blindness in a monkey by removal of the occipital region of the brain; two years after the operation the animal recovered, to a slight extent, its sight. Upon examining the brain at the seat of the lesion, he found a tissue of new formation; this tissue was very vascular, and its extirpation reproduced the blindness. Histological examination of this tissue showed the presence of nervous elements, which the author regarded as of true new formation.

Dr. Demoor (Brussels) stained the brains of animals to which he had given a strong dose of morphine or chloral hydrate by Golgi's method. Demoor found that the plotoplasm of the cell processes in these animals presented a characteristic mannilliform aspect, which was not to be observed in normal animals. The author showed his preparations

Monday Afternoon.—Presidents, Prof. Hensen and Mosso.—Prof. Herzen (Lausanne) described the characters of a gastric juice obtained by the author and Dr. Fremont (Vichy) from the isolated stomach of a dog. The œsophagus was sutured to the duodenum, and a fistula was made, from which the gastric juice was collected. The juice was without smell or colour, was highly acid, and could digest its own weight of coagulated albumin. The author further gave the result of his researches on the influence of the spleen on pancreatic digestion. He found a given quantity of blood from the splenic vein, added to a pancreatic infusion, greatly increased its digestive power, whereas the same quantity of ordinary arterial blood did not.

Prof. Schiff (Geneva) discussed the effects of an isolated lesion of one pyramid, and showed that it produced degeneration in the pyramid only, and not in the pyramidal tract.

Dr. Gurber (Würzburg) described the results of his researches on the crystallisation of serum albumin. He treated horse serum after Hofmeister's method (ammonium sulphate), and obtained four kinds of crystals. The author showed diagrams of these, and gave the results of their analysis.

Prof. Tigerstedt (Stockholm) described a new apparatus, on the principle of Pettenkofer and Voit, for respiration experiments on man. The author's apparatus is of such volume as to be able to contain several men at the same time.

Tuesday Morning.—Presidents, Prof. Rutherford and Hegir.—Dr. His, junr. (Leipsig) supported Engelmann's view that the propagation of the rhythmic cardiac wave takes place from fibre to fibre. He could not confirm Kent's results. He found in mammals, including man, a single muscular bundle which showed cross striation, going from the inter-auricular down into

the inter-ventricular septum, in the neighbourhood of a cusp of the mitral valve. The author divided this bundle by a transverse incision of 2 mm., and found that after this the auricle and ventricle beat each with its own rhythm. This bundle contained no nervous elements.

Dr. Kaiser (Heidelberg) showed that upon pinching off the lower two-thirds of the partially emptied frog's ventricle, this portion remained motionless; but on subsequently clamping the bulbus arteriosus, tension being produced in the ventricle, it recommenced to beat. Dr. Kaiser explains this result by supposing the existence in the frog's heart of a series of neurons which are discharged by an impulse which starts in the sinus, so that the mechanism is that of a reflex action: he believes the pinching destroyed the continuity of the nervous apparatus, while it left the muscle intact.

Prof. Kronecker (Bern) demonstrated in a most striking manner the effect of a sudden arrest of the coronary circulation, by injecting paraffin melting at 39° C. into the descending coronary artery. The heart at once stops and enters into marked fibrillar contraction, from which, except occasionally in young animals, it never recovers. This effect is not produced by ligature of the same artery; this, in Prof. Kronecker's opinion, is due to collateral circulation being at once established. From this experiment Kronecker infers that the cardiac rhythm is due to the activity of some structures which are exceedingly sensitive to sudden cessation of their blood supply; this is not true of muscles or nerve trunks, but is of a nerve plexus or a ganglion cell.

Dr. Magnus (Heidelburg) showed a sphygmograph for use on a dissected out artery.

Prof. Hurthle (Breslau) showed a new method of registering the arterial blood-pressure in man. The arm is made bloodless by means of an Esmark's bandage, and introduced into a phlethysmograph connected with a tambour. Hurthle also showed a method for simultaneously recording the heart movements and rendering audible the heart sounds. The latter was effected by a resonating box placed against the chest-wall; to the box a wooden tuning-fork was attached; the limbs of this vibrated in unison with the heart sounds, and varied the intensity of a current led through the primary coil of an induction apparatus, and through a microphone placed between the limbs of the fork; a telephone was connected with the secondary coil.

Dr. White (London) made experiments to show that perfect cardiac perfusion was not obtained with a Kronecker's canula as modified by Williams, the actual perfusion in a Williams' only extending to the top of the end-piece.

Dr. Zuntz (Berlin) described a new method for determining the velocity of the blood; it consisted in injecting into the carotid artery, during arrest of the heart produced by stimulation of the vagus, sufficient blood to bring the blood pressure back to the normal. Knowing the amount of blood which has to be injected, and the time this takes, the velocity of the blood, as well as the amount propelled by the heart, can be deduced.

Tuesday Afternoon.—Presidents, Profs. Wedensky and Tigerstedt. Dr. A. Dastre (Paris) showed that if fresh fibrin is placed in strong neutral saline solutions, one finds after a certain time two globulins in the solution. (1) Globulin coagulating at 54°; (2) Globulin having the properties of serum globulin; and further, that proteose and true peptone are also present. This action of saline solutions on fresh fibrin can be divided into different stages. If fresh fibrin be submitted in the same manner to the action of the digestive juices, the same results are produced; it is then quite justifiable to speak of a "saline digestion" of fibrin. Fibrin submitted to the action of oxygenated water, and to that of micro-organisms, gave the same results. When gelatin is similarly treated, gelatoses are produced, and the gelatin loses its power of coagulation.

Dr. A. Beck (Lemberg) discussed the velocity of blood in the portal vein. The author found that the normal velocity was from 2000 to 2800 cms. per second, and that 0·62-0·79 grm. of blood flowed through 1 grm. of liver tissue in twenty-four hours. The author used Cybulsky's method.

Prof. Berry Haycraft (Cardiff) read a paper on the change of shape of the heart during contraction. The author found it difficult to kill animals with the heart in systole: this he finally did by injections of $HgCl_2$. Killing animals with the heart in diastole presented no difficulty. The animals were frozen immediately after death, and sections of their hearts cut at different levels. The author's results confirmed those of Ludwig and Hesser.

Prof. F. Gotch (Oxford). The discharge of *Malapterurus electricus*. The electrical discharge of the organ evoked in the living fish by mechanical and electrical stimulation was investigated by the capillary electrometer, the frog nerve muscle galvanoscope, and the galvanometer. Each apparently single shock of the organ was found to be multiple in character, showing an initial primary, followed by several secondary electrical outbursts. The primary outburst had a latency of 4/1000" and a duration of 2/1000". The E.M.F. = 120 to 200 volts. The secondary effects which follow the primary are plainly perceptible in the isolated organ after killing the fish; hence the multiple character of the single *secousse* is due to the organ itself. Each of the secondary effects occurs at an interval of from 4/1000"-6/1000" after its predecessor. The primary as well as the secondary effects are monophasic in character; hence a very profound physiological effect is produced.

F. W. Tunnicliffe.

FORTHCOMING BOOKS OF SCIENCE.

Messrs. C. Griffin & Co., Ltd., will shortly issue:—An exhaustive treatise on "Petroleum: the Geographical Distribution, Geological Occurrence, Chemistry, Refining, and Testing, &c.," by Boverton Redwood and Geo. T. Holloway, in two volumes: "The Chemistry of Gas Manufacture: a Handbook on the Production, Purification, and Testing of Illuminating Gas, and the Assay of the Bye-Products of Gas Manufacture," by W. J. Atkinson Butterfield; "Chemistry for Engineers and Manufacturers," by Bloxam Blount and A. G. Bloxam, in two volumes: vol. i. "The Chemistry of Engineering, Building, and Metallurgy"; vol. ii. "The Chemistry of Manufacturing Processes"; "Electrical Measurements and Instruments: a Practical Handbook of Testing for the Electrical Engineer," by Charles H. Yeaman; "Textile Printing: a Practical Manual of the Processes used in the Printing of Cotton, Woollen, and Silk Fabrics," by C. S. Seymour Rothwell, with illustrative specimens (companion volume to the "Manual of Dyeing," by Messrs. Knecht and Rawson); "Bleaching and Calico-Printing: a Short Manual for Practical Men," by Geo. Duerr, with specimens designed specially to show various stages of the processes described; a third edition, revised and enlarged, of the "Outlines of Practical Physiology," by Dr. William Stirling; a fourth edition of "Foods: their Composition and Analysis," and a third edition of "Poisons: their Effects and Detection," both enlarged and revised, by A. Wynter Blyth; an eleventh edition, revised, of Munro and Jamieson's "Electrical Pocket-book"; a third edition, also revised, of Seaton and Rownthwaite's "Marine Engineering Pocket-book"; a new issue, revised, of "Griffin's Electrical Engineer's Price-book," brought up to date and edited by H. J. Dowsing; a second edition, revised, of "The Design of Structures," by S. Anglin; and the thirteenth annual issue of "The Year-book of Scientific and Learned Societies of Great Britain and Ireland," comprising Lists of the Papers read before Societies engaged in Fourteen Departments of Research during 1895.

In the Cambridge University Press's announcements we notice a series of volumes dealing with geographical and cognate subjects, which will be under the general editorship of Dr. F. H. H. Guillemard. The first volume will be by Prof. A. H. Keane, and will treat of Ethnology. This will be followed by "The Geographical Distribution of Mammals," by R. Lydekker. Mr. H. F. Tozer is to write on the "History of Ancient Geography"; and other volumes will deal with the "Renaissance Period of Geographical Discovery," by C. E. Ravenstein, and "Oceanography," by J. Y. Buchanan.; "The Scientific Papers of John Couch Adams," vol. i., edited by Prof. William Grylls Adams, with a memoir by Dr. J. W. L. Glaisher; "The Collected Mathematical Papers of the late Arthur Cayley," vol. ix.; "A Treatise on Spherical Astronomy," by Sir Robert S. Ball; "Catalogue of Scientific Papers compiled by the Royal Society of London," 1874–1883, vol. xi.; a second edition of Heath's "Treatise on Geometrical Optics; "A Treatise on Abel's Theorem," by H. F. Baker; "A Treatise on the Lunar Theory," by E. W. Brown; "An Elementary Treatise on Electricity and Magnetism," by Prof. J. J. Thomson; "A Treatise on Geometrical Optics," by R. A. Herman. In the Pitt Press Mathematical Series: "Euclid," books xi. and

xii., by H. M. Taylor; and in the "Cambridge Natural Science Manuals: "Mechanics and Hydrostatics: Part iii. Hydrostatics," by R. T. Glazebrook; "Electricity and Magnetism," by the same; "Solution and Electrolysis," by W. C. D. Whetham; "Sound," by J. W. Capstick; "Fossil Plants: a Manual for Students of Botany and Geology," by A. C. Seward; "The Vetebrate Skeleton," by S. H. Reynolds; "Text-Book of Physical Anthropology," by Prof. Macalister; and a second edition of "Practical Physiology of Plants," by F. Darwin and E. H. Acton.

Messrs. Swan Sonnenschein and Co.'s list includes:—"Text-Book of Embryology: Invertebrates," by Drs. Korschelt and Heider, part i., translated and edited by Dr. E. L. Mark and Dr. W. M. Woodworth, with additions by author and translators; parts ii. and iii. translated and edited by H. T. Campbell; "Text-book of Palæontology for Zoological Students," by Theodore T. Groom, illustrated; "The Indian Calendar," containing complete tables for the verification of Hindu and Muhammedan dates for a period of 1600 years (A.D. 300 to 1900) for the whole of India, by Robert Sewell, of the Madras Civil Service, in collaboration with Sankara Bâlkrishna Dikshit, with a table of eclipses by Dr. Schram; "Practical Plant Physiology," by Prof. Wilhelm Detmer, translated by S. A. Moor; "Introductory Science Text-books"—"Zoology," by B. Lindsay, with illustrations and diagrams; "Elementary Biology," by Dr. H. J. Campbell, second edition, with appendix; "Organic Chemistry," by J. Wade; Young Collector Series: "Fishes," by the Rev. H. A. Macpherson; "Mammalia," by the Rev. H. A. Macpherson; "Birds' Eggs and Nests," by W. C. J. Ruskin Butterfield.

Messrs. Longmans and Co.'s forthcoming books include:—"The Romance of the Woods: reprinted Articles and Sketches," by Fred. J. Whishaw; "The Life of Joseph Wolf, Artist and Naturalist," by A. H. Palmer; "The Life of Sir Henry Halford, Bart., F.R.S., President of the Royal College of Physicians, Physician to George III., George IV., William IV., and to Her Majesty Queen Victoria," by Dr. William Munk; "Darwin, and After Darwin: an Exposition of the Darwinian Theory, and a Discussion on Post-Darwinian Questions," by the late Dr. George John Romanes, F.R.S. Part ii. Post-Darwinian Questions: Heredity and Utility; "The Life and Letters of George John Romanes, F.R.S.," written and edited by his Wife; "Studies of Childhood," by Prof. James Sully; and in a new series of "Physical and Electrical Engineering Laboratory Manuals," "Elementary Physics," by John Henderson; "The Magnetic Circuit in Theory and Practice," by Dr. H. du Bois, translated from the German by Dr. E. Atkinson.

Messrs. George Philip and Son's announcements include:—*Maps*—Topographical Map of the Argentine Republic, in 10 sheets, scale 1 : 2,000,000, by H. D. Hoskold. Geological Map of the British Isles, forming part of the International Geological Map of Europe, scale 1 : 1,500,000. Philip's Topographical Map of England and Wales, in 40 sheets, scale 1 : 200,000. Philip's Library Map of India, scale 1 : 5,000,000. Philip's Large Map of Western Australia, scale 1 : 1,500,000. Philip's New Map of Liverpool, scale 6 inches to 1 mile. *Books*—"Telescopic Astronomy," by A. Fowler; "The Anatomy of the Human Head and Neck," illustrated by means of movable coloured plates, with description, by William S. Furneaux; "The Ox," its external and internal organisation, illustrated by means of movable coloured plates, with description, by Prof. G. T. Brown; "The Oarsman's Guide to the Navigable Rivers and Canals of the British Isles," by Members of the Cruising Club.

Messrs. Crosby Lockwood and Son hope to issue:—"Rural Water Supply: a Practical Hand-book on the Supply of Water and Construction of Water Works for Small Country Districts," by Allan Greenwell and W. T. Curry; "Dangerous Goods: their Sources and Properties, and Modes of Storage and Transport," by H. Joshua Phillips; "Practical Masonry: a Treatise on the Art of Stone-cutting," comprising the construction, setting out, and working of stairs, arches, niches, domes, &c., with fifty lithographic plates, by Wm. R. Purchase; "Refrigerating and Ice-Making Machinery," by A. J. Wallis-Tayler; and new editions of "The Metallurgy of Gold," by M. Eissler, with twenty-five additional plates and working drawings, and chapters on recent milling operations in the Transvaal, and the future outlook in the South African Gold-fields; and "Practical Tunnelling," by F. Simms, with large additions on recent tunnelling practice by D. K. Clark.

We find in the list of the S.P.C.K.:—"The Romance of Science" Series, "The Splash of a Drop," by Prof. Worthington, with numerous diagrams; "The Work of the Spectroscope," by Dr. Huggins; "Time," by Prof. Boys. Manuals of Science "Physiology," by Prof. Macalister; "Ancient History from the Monuments: Babylonia," by Prof. Sayce, a new edition, edited and brought up to date; "Simple Methods for Detecting Food Adulteration," by J. A. Bower, with diagrams; "Gosse's Evenings at the Microscope," a new edition, revised by Prof. F. Jeffrey Bell; "Iceberg, Prairie and Peak: some Gleanings from an Emigrant Chaplain's Log," by the Rev. Alexander A. Boddy; "The Zoo," vol. iv., by the Rev. T. Wood, with coloured illustrations.

Among Messrs. A. and C. Black's new books will be:—The last part of Prof. Newton's "Dictionary of Birds"; "Artistic and Scientific Taxidermy and Modelling," by Montagu Browne; Vol. i. of "Zoology," by Prof. Ray Lankester; "Text-book of General Pathology and Pathological Anatomy," by Prof. R. Thoma, translated by Dr. Alexander Bruce, two volumes, illustrated; "Introduction to the Study of Fungi," by Dr. M. C. Cooke, illustrated; "Dynamics," by Prof. P. G. Tait; "Milk: its Nature and Composition," by Dr. C. M. Aikman, illustrated; and a new edition of "Black's General Atlas of the World," with twenty-six additional maps of the North American States.

Messrs. Cassell and Co., Limited, promise:—The Century Science Series, edited by Sir Henry Roscoe, F.R.S.; "Charles Lyell: his Life and Work," by Prof. T. G. Bonney, F.R.S.; "British Birds' Nests: How, Where, and When to Find and Identify them," by R. Kearton, with illustrations of nests, eggs, young, &c., in their natural situations and surroundings; "Popular History of Animals for Young People," by Henry Scherren, with thirteen coloured plates and numerous illustrations in the text; "The Year-book of Treatment for 1896," twelfth year of publication, illustrated.

The Religious Tract Society promises: "Rambles in Japan: the Land of the Rising Sun," by Canon Tristram, with forty-five illustrations; "A Visit to Bashan and Argob," by Major Algernon Heber-Percy, illustrated; "Plants of the Bible," by Rev. George Henslow, illustrated; "A Primer of Hebrew Antiquities," by Rev. O. C. Whitehouse, illustrated; "Hidden Beauties of Nature," by Richard Kerr, illustrated; "Consider the Heavens: a Popular Introduction to Astronomy," by Mrs. William Steadman Aldis, illustrated; "A Popular Handbook to the Microscope," by Lewis Wright, illustrated, "Lighthouses: their History and Romance," by W. J. Hardy, illustrated.

Messrs. Sampson Low and Co. will publish by subscription "Twentieth Century Practice: an International Encyclopædia of Modern Medical Science," by leading authorities of Europe and America, edited by Dr. Thomas L. Stedman, in twenty volumes. Their other scientific publications include the second edition of "A History of Scandinavian Fishes"; "A Manual of Obstetric Nursing," by Marian Humfrey, vol. ii., and new editions of Hofmann's "Treatise on Paper-Making," and Davis's "Practical Treatise on the Manufacture of Brick, Tiles, and Terra-Cotta," both fully illustrated.

Messrs. Whittaker and Co. announce the following works:—"Transformers for Single and Polyphase Alternating Currents," by Gisbert Kapp, translated from the German; "The Inspection of Railway Material," by G. R. Bodmer; "The Chemist's Compendium, a Pocket-book for Pharmacists and Students," by C. J. S. Thompson; "Modern Printing, a complete handbook of printing," by J. Southward; a new and enlarged edition of "Coal-pits and Pitmen," by R. Nelson Boyd; "A Practical Trigonometry for the use of Engineers, Architects, and Surveyors," by Henry Adams.

Messrs. Rivington, Percival, and Co. will issue:—"Clinical Illustrations of the Diseases of the Fallopian Tubes and of Tubal Gestation," by Dr. C. J. Cullingworth; "Mensuration," by Rev. A. D. Clarke; "Beginner's Text-Books of Science" Series, "Chemistry," by G. Stallard; "Geology," by C. L. Barnes; "Electricity and Magnetism," by L. Cumming; "Heat," by G. Stallard; "Mechanics" (treated experimentally), by L. Cumming; "Physical Geography," by C. L. Barnes.

In Messrs. Putman's Son's list we find:—"Wild Flowers of the North-Eastern States," drawn and carefully described from life, by Margaret C. Whiting and Ellen Miller, with 308

...ustrations: "A Natural Method of Physical Training," by Edwin Checkley, illustrated from photographs, new edition; "The Law of Psychic Phenomena," a working hypothesis for the study of hypnotism, spiritism, mental therapeutics, &c., by T. J. Hudson.

The Clarendon Press has in active preparation:—"A New English Dictionary," portions of D, edited by Dr. J. A. H. Murray, and of F, edited by H. Bradley; "British Moralists of the Eighteenth Century," edited by L. A. Selby-Bigge, two vols.; "Index Kewensis," compiled at the expense of the late C. R. Darwin, under the direction of Sir Joseph D. Hooker, by B. Daydon Jackson, two vols.; and "An Introduction to the Algebra of Quantics," by E. B. Elliott.

Messrs. G. Bell and Sons have in the press:—"The Mechanism of Men-of-War," by Fleet-Engineer R. C. Oldknow, R.N.; "Torpedoes, Torpedo Boats, and Torpedo Warfare," by Lieut. J. Armstrong, R.N.; "Naval Gunnery," by Capt. H. G. Garbett, R.N.; "Naval Architecture, the Designing and Construction of a Warship," by J. J. Welch; "Logic: a Handbook for the Use of Students," by F. Ryland; "Gas Manufacture," by J. Hornby.

Messrs. James MacLehose and Sons, Glasgow, have in preparation a volume on "Deaf-mutism, including Chapters on the Education of Deaf Mutes," by Dr. J. K. Love and W. H. Addison; a new edition of a "Treatise on Diseases of the Ear," by Dr. Thos. Barr; "An Account of the Institution and Progress of the Faculty of Physicians and Surgeons of Glasgow," by Alexander Duncan.

Messrs. W. Blackwood and Sons' announcements include:—"Introductory Text-Books of Meteorology," by Dr. A. Buchan, new edition, with coloured charts and engravings; Page's "Advanced Text-Book of Geology," new edition, revised and enlarged by Prof. Lapworth; Dr. Mackay's "Elements of Physiography," rewritten and enlarged, "Elementary Algebra," "Mental Arithmetic."

The following additions will be made to Messrs. George Newnes' "Library of Useful Stories": "The Story of the Earth in Past Ages," by Prof. H. G. Seeley, with original illustrations from the author's collection; and "The Story of the Solar System," by George F. Chambers.

Mr. Edward Arnold will issue:—"The Exploration of the Caucasus," by D. W. Freshfield, in two volumes, illustrated; "Cycling for Health and Pleasure," by L. H. Porter, revised; and "Strength; or, the Development and Use of Muscle," by C. A. Sampson.

Messrs. W. and R. Chambers's list contains:—Eminent Engineers: "Lives of Watt, Stephenson, Telford, and Brindley"; "Thomas Alva Edison: the Story of his Life and Inventions"; a re-issue of Chambers's Encyclopædia, in ten monthly volumes.

Mr. Fisher Unwin gives notice of: "The Evergreen: a Northern Seasonal," part ii.; "Electricity for Everybody," illustrated. The Criminology Series. (2) "Criminal Sociology," by Prof. E. Ferri; (3) "Our Juvenile Offenders," by W. Douglas Morrison.

Messrs. A. D. Innes and Co. will publish: "A Naturalist in Mid Africa," by G. F. Scott Elliot, with numerous illustrations.

To Mr. Walter Scott's "Contemporary Science Series" will be added "Evolution in Art, as illustrated by the Life-Histories of Designs," by Prof. A. C. Haddon.

Messrs. W. H. Allen and Co. have in preparation:—"Ferns, British and Foreign," by John Smith, and a new edition of Herschel's "Popular Lectures on Scientific Subjects."

In Messrs. Macmillan and Co.'s announcements we find the following: "Sir Joseph Banks's Journal," selections edited by Sir Joseph Hooker, K.C.S.I., F.R.S.; "Sketches in Sport and Natural History," by the late Dr. George Kingsley, with memoir by his son Charles Kingsley; "A History of Mankind," by Prof. Friedrich Ratzel, translated from the second German edition by A. J. Butler, with preface by Dr. E. B. Tylor, with thirty coloured plates, maps, and numerous illustrations in the text, in thirty monthly parts, and in three vols.; "Studies in the Art Anatomy of Animals," by Ernest E. Thompson, illustrated; "The Cambridge Natural History," edited by S. F. Harmer and A. E. Shipley, vol. v., Peripatus, by A. Sedgwick, F.R.S., Centipedes, &c., by F. G. Sinclair, Insects, by D. Sharp, F.R.S.; "The Structure and Development of the Mosses and Ferns (Archegoniatæ)," by Dr. Douglas Houghton Campbell; "The Scenery of Switzerland," by Sir John Lubbock; "A Handbook of British Lepidoptera," by Edward Meyrick; "The Structure of Man," by Prof. Wiedersheim, translated by H. M. Bernard, and edited by Prof. G. B. Howes, illustrated; "A Text-book of Comparative Anatomy," by Dr. Arnold Lang, translated into English by Henry M. Bernard and Matilda Bernard, vol. ii.; "Dictionary of Chemical Solubilities," by Dr. Comey; "A System of Medicine," edited by Dr. T. Clifford Allbutt, F.R.S., five vols; "A System of Gynæcology," edited by Dr. William Playfair and Dr. T. Clifford Allbutt, F.R.S.; "Elements of Palæontology," by Prof. Karl A. von Zittel, translated and edited by Dr. Charles R. Eastman; "Principles of Mechanics," by the late Prof. H. Hertz, translated by D. E. Jones; "Evolution and Man's Place in Nature," by Rev. Dr. Henry Calderwood, second edition, in great part rewritten; "Miscellaneous Papers," by the late Prof. H. Hertz, translated by D. E. Jones; "Electro-Physiology," by Prof. W. Biedermann, translated by Miss F. A. Wells; "The Scientific Basis of Analytical Chemistry," by Prof. Wilhelm Ostwald, translated by Dr. George MacGowan; "Text-book of Botany," by Prof. Strasburger and others, translated by Dr. H. C. Porter; "The Life of Agassiz," by Jules Marcou, two vols.; "Columbia College, Contributions to Philosophy, Psychology, and Education"; Columbia University Biological Series: "Fishes, Living and Fossil," by Dr. Bashford Dean; Columbia University Press Publications: "Statistics and Sociology," by Prof. Richmond Mayo-Smith; "An Atlas of Fertilization," by Prof. Edmund B. Wilson; "Elements of Geometry," by George C. Edwards; "The Theory of Sociology," by F. H. Giddings; "Alternating Currents," by D. C. Jackson; "A Laboratory Course in Experimental Physics," by W. J. Loudon and J. C. McLennan; "An Exercise Book of Elementary Practical Physics," by R. A. Gregory; "Elementary Text-book of Physical Geography for High Schools," by R. S. Tarr.

GEOLOGY AT THE BRITISH ASSOCIATION.

AFTER the presidential address, which was of great local interest, and listened to with much attention by a large audience, Mr. Harmer read two papers bearing on the Coralline and Red Crags. This veteran geologist, who, with the late Mr. Searles Wood, jun., did so much to unravel the age of the various Tertiary deposits in East Anglia, rendered much service to the Section, not only by the contribution of papers and in the discussions, but by attending the numerous excursions, and placing his knowledge and experience at the service of those less acquainted with Pliocene and Pleistocene rocks.

Taking the 240 more abundant molluscan species found in the Coralline Crag apart from those which are represented by rare or even unique species, he finds that their assemblage points, more distinctly than the mere aggregate of fossils, to the Southern character of the fauna; 57 per cent. being extinct, only one species is not found south of Britain, and not less than 36 per cent. are characteristically Southern. The following summary gives the principal facts on which this conclusion is based.

Summary of the abundant and characteristic Species of Mollusca occurring in the Coralline Crag.

Not known as living (37 per cent.)	89
Living in distant seas	8
,, ,, the Mediterranean	133
,, ,, the West European area	9
,, not south of Britain	1
Total	240

Species of European Mollusca occurring abundantly in the Coralline Crag.

Southern and not British (28 per cent.) ...	42
British (rare) and Southern	9
(35 per cent.) ...	51
British (characteristic) and Southern ...	91
,, and not Southern	1
Total	143
Total number of species	436

In his second paper, Mr. Harmer acknowledged that the Eocene shells, and probably some others found in the nodule bed at Waldringfield, were undoubtedly derivative; but he contended that it was possible that others belonged to the period which elapsed between the deposition of the Red Crag at Walton and that at Butley. This conclusion was mainly based on the fact that many of them are found *in situ* in the Belgian Crags of this age.

Mr. Burrows followed with a paper on the distribution of Foraminifera in the Crags. In the Upper Crag, or Newer Pliocene, there are 29 species of common North Atlantic Foraminifera; in the Red Crag 20 species; and in the St. Erth beds 163, of which 66 occur also in the Coralline Crag. Some of the Coralline Crag Foraminifera appear to have been derived from older deposits. Notes were given on the age of the different portions of the Coralline Crag now or formerly exposed at several important localities.

Next came two papers on Southwold; the first by Mr. H. B. Woodward, on a section recently exposed by denudation at the North Cliff, and a second on recent coast erosion there, by Mr. Spiller. The Norwich Crag is succeeded by chalky boulder clay, and that by a fresh-water loam, peaty earth, and a recent beach deposit, in which a human skeleton was found this year. Mr. Spiller's paper gave an account of the erosion of the North Cliff during a storm in May last, and by measurements taken since, and comparison with a map previously made by Mr. Whitaker, he concluded that different points on the coast had been eroded at the following rate:—

		Feet.
Easton Bavents	Loss in 6 years ...	20
Easton High Cliff ...	,, 13 ,, ...	22
Covehithe Cliff	,, 6 ,, ...	84

In two short papers which followed, the Rev. E. Hill attributed the formation of some boulder clays to rapid deposit by the agency of water under the influence of floating ice and ice-rafts, a conclusion strongly controverted by several advocates of the land-ice theory who were present. A third paper, by the same author, described traces of an ancient watercourse seven miles long in Suffolk.

A paper, by Messrs. Reid and Ridley, described their recent researches by boring, and an examination of the deposits above the water-level, at Hoxne. The following is the section disclosed, revealing the apparent existence of a temperate flora between the morainic deposits and the Arctic plant bed. A grant was made by the Association to enable Mr. Reid to continue this work, with a view of determining the relation of the Palæolithic remains to the Glacial epoch.

		Feet.
Gravelly surface soil	about	2
Brick-earth; towards the base *Valvata piscinalis*, cyprids, bones of ox, horse, elephant (?), and Palæolithic implements	about	12
Sandy gravel, sometimes carbonaceous, with flint flakes	about	1
Peaty clay, with leaves of Arctic plants (?) ...	about	4
Lignite, with wood of yew, oak (?), white birch, and seeds of cornel, &c.	about	1
Green calcareous clay, with fish, *Valvata piscinalis*, *Bythinia tentaculata*, cyprids, *Ranunculus repens*, *Carex*	about	4
Boulder clay.		

The day's work was closed by a paper from the President, on some Suffolk wells, six of which penetrate some distance into the chalk.

Tuesday was devoted almost exclusively to papers on glacial subjects, opening with an interesting communication by Prof. Sollas on artificial glaciers, or "poissiers," made of pitch. This paper was illustrated by pitch models split longitudinally, lantern photographs, and models in Canada balsam, images of which could be thrown on the screen. The main point to which attention was directed was the power of the viscous substance to carry grains of rice, sand, or pigment uphill when confronted by a barrier, or when driven into a narrow gorge. The conclusion drawn was that ice and pitch conformed to the laws of fluid motion, and this was further illustrated by the flow of water over a raised model of Ireland, when the currents conformed to the directions of former ice movement. The pitch sometimes travelled over heaps of loose material without disturbing them.

Mr. Clement Reid followed with some illustrations of the glacial sections at Cromer, showing the great chalk boulders, the contortion of the chalk, and the contortion, crushing, brecciation, and shearing of the boulder clay at that locality. Prof. W. B. Scott gave an illustrated description of the "Bad Lands," and showed that this area was in Tertiary times the site of a succession of great lakes whose history extended from the beginning of the Eocene period up to Pleistocene times. Evidence of change in climate is given by the gradual disappearance of palms, and the diminution in numbers and variety of the reptiles. A paper by Mr. R. B. White described various deposits in Colombia (New Granada) to which he attributed a glacial origin; he recognises moraines, erratic blocks, breccias and conglomerates, in places mostly made up of volcanic materials, but elsewhere made of the débris of sedimentary rocks. The paper concluded with some novel speculations as to the cause of the Ice Age.

Mr. B. Thompson described a number of pre-glacial valleys Northamptonshire, belonging to the following chief types. New valleys without drift and having old filled-up valleys near at hand: (2) valleys with rock on one side and drift on the other; (3) streams re-excavating old, drift-filled, valleys; (4) re-excavated valleys with the drift only left in the form of river-gravel derived from it. In his account of some Snowdonian tarns, Mr. W. W. Watts concluded that one of the shallow lakes in Cwm Glas was in a very shallow rock-basin, and the other dammed by scree- and stream-detritus. Glaslyn and Llyn Llydaw, though finding exit over moraine, had rock-barriers at depths of from thirty to fifty feet below the lake surface, so that they are either confined in true rock-basins, or else are very much shallower than is generally supposed.

The Committee for exploring the supposed glacial shell-bed at Clava, hoped to bring important results out within the year, and that engaged in exploring the Calf Hole cave also hoped to finish its lists of fossils in the same period. In reporting on the high-level flint drift near Ightham, Mr. Harrison described excavations made into a gravel 658 feet above the sea on the face of the chalk escarpment: worked flints, chiefly scrapers and flakes, were found in great quantity. In the discussion Sir John Evans expressed scepticism as to the human origin of the supposed worked flints.

The Committee on Coast Erosion published a final report which contains an abstract of previous reports, and a considerable amount of new information from Kent, Suffolk, Sussex, Hampshire, Norfolk, Yorkshire, the Northern counties, Lancashire, and North Wales. The Committee concludes that the work of devastation is much aided by the abstraction of shingle and sand, and also by the erection of unsatisfactory sea-walls and groynes. They further recommend that the subject should become the work of a departmental Committee of the House of Commons. The twenty-first and final report of another long-standing Committee gives a useful summary of principles guiding underground water supply, and then resigns its task to the local scientific societies, which are urged to communicate all information received to the Geological Survey Office at Jermyn-street, where careful records are now kept. Such a course naturally will give increased value to the information daily supplied to inquirers from that office. In the last paper Mr. Holmes gave further information on an ancient silted-up stream course which flowed between the high ground of Warley, Billericay, and Maldon on the one hand, and that of Laindon, Rayleigh, and Althorne on the other, into the Blackwater. The deposits of this river were covered by the highest (oldest) gravel terrace of the Thames system. A paper by Messrs. Lomas and Kendall dealt with the striæ produced by modern glaciers.

The first paper on Saturday was that of Prof. Marsh on some European Dinosaurs. He exhibited a diagram placing American and European forms side by side, and showing that the European types filled up gaps in the American series. In many of his restorations he differed decidedly from those which have been previously published, some of which he characterised as being like nothing "in heaven above, or in the earth beneath, or in the waters under the earth." The Connecticut Triassic footprints he attributed to Dinosaurs and not birds. The Committee appointed to endeavour to recover the missing portions of the Cetiosaurus skeleton in the Oxford Museum had been unable to carry out their work within the year, but they had now determined on their course of action, and obtained the requisite permission, so that they hoped to complete the work before the Liverpool meeting. Mr. Montagu Browne communicated a description of a section

on the new Manchester, Sheffield, and Lincolnshire Railway, exposing Rhætic rocks in Nottinghamshire, and gave a list of fossils derived from these beds.

The first part of Monday's sitting was devoted to papers by authors from France and Belgium. M. G. F. Dollfus considered that in Upper Tertiary times there were two great seas in Western Europe; one was to the east, not very far from Eastern England, in Miocene times, and extended over the Netherlands and North Germany; the other, or old Atlantic, was to the west of England, and extended in gulfs into France and Portugal, probably communicating with the Mediterranean Sea along the Guadalquiver Valley. In Pliocene times the seas occupied similar positions, but the land was rather higher, and a gulf on the Atlantic side appears to have reached Cornwall. The English Channel was closed, and the Eastern Sea appears to have been open only towards the north. M. Van den Broeck's paper described the present state of knowledge of the Upper Tertiary strata of Belgium. He had determined that the Upper Oligocene strata did not exist in Belgium, but that the Upper Pliocene was probably present there. He concluded that the line of march of the Miocene fauna was from east to west, for Miocene forms present in Belgium were absent from England. That the Miocene formation had been once present in England he inferred from the fact that half the Belgian Miocene fauna was to be found in the Coralline Crag. A communication from M. M. Boule described the finding of remains of *Elephas meridionalis* and *E. antiquus* in association with worked flints, some of them of elaborate workmanship, but others of St. Acheul type, and mammoth tusks, one of which was 2·85 metres in length; one flint was found under a tusk of *E. meridionalis*.

Prof. John Milne's report on Japanese earthquakes was given in full to Section A, but a short account of his work was communicated to Section C. The author has prepared a catalogue of 8331 shocks recorded in Japan between 1885 and 1892. The instruments used have recorded earthquakes which must have travelled right through the earth with a velocity greater than if its interior were composed of glass or steel. They also indicate movements corresponding with variations in barometric pressure and strong winds, and even a diurnal variation possibly due to the evaporation of moisture and the condensation of dew.

Dr. H. J. Johnston-Lavis reported on the activity of Vesuvius during 1895. (The substance of his report has already appeared in NATURE for August 8). The Committee on coral reef exploration presented an interim report on the negotiations between the Royal Society and the Admiralty as to beginning the work of sounding and boring. Mr. Osmund Jeffs reported that a number of the geological photographs collected by his Committee had found a home at the Museum of Practical Geology in Jermyn-street, and that the rest would shortly be deposited there. Prints to the number of 1200 had been received and catalogued, but numerous localities, and particularly the Eastern Counties, were as yet poorly represented. The report contained some valuable recommendations for the apparatus suitable for continuing the work, and the Committee proposed to carry on its collection, and to make special efforts to induce local societies and individuals to fill up the blanks in the collection, and to make it a thorough photographic survey of geological phenomena throughout the United Kingdom. A valuable appendix to the report contained a list of such of the photographs as had been employed in illustrating geological works. Dr. Hatch's paper on the auriferous conglomerates of the Witwatersrand showed that gold occurred only in the matrix of these rocks, and not in the pebbles; it had probably been introduced by subsequent infiltration. Mr. E. A. Walford, in a report and paper, described the succession of limestones, clays, and sandstones which have been revealed by sinking between the Stonesfield slate and the Inferior Oolite in Oxfordshire, and traced these divisions north-west and south-east, correlating the upper calcareous division with the Fullonian, and the middle sandy division with the Northamptonshire Estuarine series.

The early part of Tuesday was devoted to papers on deep borings, and the later part to work chiefly on invertebrate palæontology. The President described the succession of rocks revealed by the experimental boring at Stutton. The section which heads the top of the next column gives that succession. The lowest rocks are likely to be of Carboniferous or Silurian age, but the absence of fossils renders it impossible to be sure which of these divisions they really belong to. The boring has now been carried down to a depth of 1356 feet, mostly in highly inclined and even vertical strata of the same doubtful character.

	Feet.
Drift (river gravel)	16
London clay and Reading beds	54
Upper and middle chalk	720
Lower chalk, with very glauconitic marl at the base (almost a green sandstone)	$154\frac{1}{2}$
Gault	$49\frac{1}{2}$
Palæozoic rock, with a high dip.	

Mr. J. Francis gave the methods and results, hitherto unpublished or incorrectly stated, of the attempt to determine the dip of strata met with in deep wells at Ware and Turnford. After rejecting various magnetic and mechanical appliances, the following device was hit upon. The boring tools were lowered with extreme precautions to prevent any torsion during the lowering, and by means of steel points connected with them the direction of a known diameter was marked by vertical chases on the circumference of the core while still *in situ*; during the raising of the tool no twisting occurred; a wax mould of the top of the core *in situ* was then taken, and again the lowering and raising were done without twisting. The core was then broken and lifted, and by means of the diameter marked on it *in situ*, confirmed by a known line on the wax mould, the direction and amount of dip was ascertained. To test the method the boring was continued, and after the top of the core had been ground to a flat surface, steel-punch marks along a known diameter, maintained by careful lowering and raising with the same precautions, were impressed on the surface, and again the core was broken and lifted. This observation was within a degree of the previous one; so that there is probably only a negligible error, or none, in the observations. The dip of the Silurian rock at Ware at 828 feet below the surface was 1° west of south, at an angle of 41°. Similar experiments at Turnford, carried out with rather less success, gave the dip of the Devonian rocks at 994 feet as 17° west of south at 25° from the horizon. These dips correspond with those of the Secondary rocks off the Wealden axis. The south-easterly dip which has been published for one of these instances is incorrect. Mr. Harmer, in a paper which followed, advocated that the survey of deep-seated rocks by borings should be systematically carried out by the Geological Survey, the expense being provided for indirectly by the appreciation of real property, and directly by royalty, wherever success attended the operations.

Prof. Claypole described some whole specimens of Cladodonts from the Devonian rocks of Ohio, which showed that many species hitherto defined from single and isolated teeth can no longer be maintained. The Upper Devonian shales of the same region have yielded many genera of large Placoderms; the head of *Dinichthys* measured from 2 to 3 feet in length; *Titanichthys* was still longer; and the jaws of *Gorgonichthys* alone measured 24 inches in length, ending in teeth or points from 6 to 9 inches in length. All these genera are closely allied to *Coccosteus*.

One of the most important papers of the meeting was that by Prof. Nicholson and Mr. Marr on the Phylogeny of the Graptolites. They are led to believe that a character of essential importance in dealing with the classification of the Graptolites, and one which, in all probability, indicates the true line of descent, is found in the shape and structure of the hydrothecæ, the point of next importance as indicating genetic relationship being the "angle of divergence"! These views are illustrated by reference to forms belonging to the "genera" *Bryograptus*, *Diplograptus*, *Tetragraptus*, and *Didymograptus*, which appear in turn in this sequence. Out of nine *Tetragrapti* (and the authors know of no other forms referred to this genus which are represented by well-preserved examples), eight are closely represented by forms of *Didymograptus*, which are closely comparable with them as regards characters of hydrothecæ and amount of "angle of divergence," whilst the ninth is comparable with a *Didymograptus* as regards "angle of divergence" only. Moreover, four of the *Tetragrapti* are comparable as regards the two above-named important characters with forms of *Dichograptus* and *Bryograptus* with eight or more branches, and the authors confidently predict the discovery of forms belonging to these or closely allied many-branched "genera," agreeing with the remaining *Tetragrapti* in what they regard as essential characters. They give details showing points of agreement of each group of the various series, including a two-branched, a four-branched, and a many-branched form, and point out how difficult it is to understand how the extraordinary resemblances between the various species of *Tetragraptus* and *Didymograptus* (to take one example) have

arisen, if, as usually supposed, all the species of a "genus" have descended from a common ancestral for each genus, in the one case four-branched, and in the other case two-branched. On the other hand, it is comparatively easy to explain the more or less simultaneous existence of forms possessing the same number of stipes, but otherwise only distantly related, if they are different ancestral types. Phenomena somewhat analogous have been detected amongst the species of Ammonites and Brachiopods. Following these inferences to their legitimate conclusion, the authors point out how "genera," like *Diplograptus* and *Monograptus*, may contain representatives of more than one "family" of graptolites according to the classification now in vogue, which would account for the great diversity in the characters in the monograptid hydrothecæ.

Messrs. Garwood and Muir followed with a paper on the zonal divisions of the Carboniferous system. The following zones are recognised by them :—

Zone of *Productus* c.f. *edelburgensis.*
,, ,, *latissimus.*
,, ,, *giganteus.*
,, *Chonetes papilionacea.*
,, *Spirifera octoplicata.*

Mr. Garwood has traced the zone of *P. latissimus* occupying the same position relative to that of *P. giganteus* from Settle, in Yorkshire, to the Northumbrian coast, near Howick Burn. In conclusion, the authors hope that their work may be continued by a Committee, and one was appointed by the Section and confirmed by the General Committee of the Association.

Prof. T. Rupert Jones, in the twelfth report on Palæozoic Phyllopoda, gave a *résumé* of these organisms referred to in previous reports, and appended some valuable notes and two tables by Prof. Lapworth, of which the first gives a general correlation table of the Lower Palæozoic rocks ; the second, the horizons of the chief species of Phyllopods. A third table gives a list of the geological order of species. After hearing interim reports from the Committees on Eurypterids, and on type specimens, the Section listened to a paper by Dr. Woodward on Decapod Crustaceans from the Cretaceous rocks of Vancouver, in which the following new species were described. *Callianassa Whiteavesii*, *Palæocorystes Harveyi*, *Plagiophthalmus(?) vancouverensis*, and *Homolopsis Richardsoni*. Many of these forms approach contemporaneous European types. The closing report was that on erratic blocks. The Yorkshire Boulder Committee and that of the Hull Geological Society are promoting a systematic survey of the ground. New work has also been done in Lincolnshire, Shropshire, Cheshire, South Wales, and Ireland.

A very pleasant feature of this year's meeting has been a series of afternoon walks or drives, carefully planned by the Local Secretary, Mr. Ridley ; in many of these the President took the leadership, and several members of the Section attended. The list of these included Bramford, Sproughton, Orford, Sudbourne, Butley and Chillesford, Woodbridge and Sutton, Tattingstone, Bawdsey, Foxhall, and Cromer. At several of these localities the sections had been freshly scarped or reopened by the Local Committee and by the landowners. It is much to be hoped that in future similar opportunities may be afforded of acquiring as full a knowledge of the geology of the neighbourhood in which the meeting is held.

ZOOLOGY AT THE BRITISH ASSOCIATION.

As this Section was occupied with dredging excursions on the Saturday and Wednesday, only four days were available for sectional meetings, and as the number of papers and reports to be discussed was large (nearly fifty), the sittings were continued late into the afternoon. The majority of the papers dealt with marine zoological subjects, and fishery questions received special attention.

After the President's address on Thursday, the following reports of Committees were taken :—

On the marine zoology, botany, and geology of the Irish Sea. The report deals with nine dredging expeditions held during the past year, and discusses the additions made to the known fauna. Statistics of the dredging results are given to show (1) the relative richness, per haul, of the shallower over the deeper waters, and (2) the relatively large number of genera represented by the species in one haul ; pointing to the conclusion that, as a rule, allied species are not found together. The submarine deposits round the Isle of Man, and the currents of the Irish Sea are also discussed.

On the migration of birds. The nine years' observations are now being tabulated for presentation at next meeting.

Investigation of the zoology of the Sandwich Islands. Valuable collections are being made and brought home, and unless these are made now they can never be done, as the extinction of much of the present fauna is not only inevitable, but will be immediate.

Research at the Zoological Station at Naples. The British Association table has been occupied by Mr. M. D. Hill, who has been investigating the maturation and fecundation of the ova of Echinodermata and Tunicata.

Research at the Marine Biological Laboratory at Plymouth. This Committee have enabled Miss Florence Buchanan to work out the blood-forming organ in the larva of Magelona ; Mr. E. J. Allen to work on the nervous system of the embryonic lobster ; and Mr. Sumner to work at the Echinoderm fauna of Plymouth.

Investigation of the fauna and flora of the West Indian Islands. The Committee reported upon the progress made in working up the collections.

On an Index Generum et Specierum Animalium. In Mr. Sherborn's hands the Index is making satisfactory progress.

On the physiological applications of the phonograph. The Committee are studying the marks on the cylinder of the phonograph by microphotographs and by recording curves, and they propose to make these available for philological purposes in the study of dialects.

The following papers were then taken :—

On the Stereornithes, by C. W. Andrews. They are a heterogeneous group of extinct birds, found in Patagonia, whose chief points of resemblance lie in their large size and reduced power of flight. Some of them, at least, have no special affinities with the living Ratitæ. They are not represented in European museums.

Facts and reflections on budding in compound Ascidians, by Prof. W. E. Ritter (California). The author argues for the polyphyletic origin of the compound Ascidians ; he considers that there is no homologue of the "epicardium" of *Clavelina* in either *Goodsiria* or *Botryllus ;* he suggests that budding has arisen in small Ascidians as a compensation for diminished power of sexual reproduction ; he believes that physiological necessities have modified the course of development by budding, so that the endoderm now produces some organs originally formed from ectoderm.

A new classification of the Tunicata, by W. Garstang. The author gave his reasons for proposing to modify the classifications given by Herdman and by Lahille, by adopting some of the features of each scheme. In the main he proposes to follow Herdman in the primary divisions, and Lahille in the subdivisions. He considers *Pyrosoma* to be related to the pelagic forms, such as *Salpa*, and not to the fixed Ascidians. He makes use of the branchial sac largely in classification. This paper gave rise to an interesting discussion.

On the presence of skeletal elements between the mandibular and hyoid arches of *Hexanchus* and *Læmargus ;* and on the presence of a sternum in *Hexanchus griseus*, by Dr. P. White.

On the Creodonta, by Prof. W. B. Scott. This and some of the other papers gave rise to considerable discussion, and the Section did not adjourn till about five o'clock.

In the course of the day's proceedings it was moved by Prof. W. A. Herdman (President of the Section), seconded by Dr. P. L. Sclater (past-President), and carried unanimously, that the zoologists of this Section desire to present to Dr. John Murray their congratulations on the completion of the *Challenger* publications, and their best thanks for his splendid services to science. This resolution was duly conveyed to Dr. Murray, and a letter of thanks from him was received by the Section later in the meeting.

Friday was devoted to papers and discussions on the marine fisheries. Prof. McIntosh led off with a paper on some of the results of scientific investigations as applied to the fisheries. He gave a useful summary of what had been effected by the Scottish Fishery Board : he showed that the three-mile limit was insufficient to protect the spawning fishes, and in conclusion urged that scientific investigations on the fisheries should be carried out by Government and not be left to Universities.

Prof. Haddon followed with a report on the Royal Dublin Society's Fishery Survey, and also gave an account of the Fishery School at Kingsend, near Dublin. He pointed out the special conditions of the Irish fishery grounds, the lack of access to markets and of fish-curing stations on the west.

Dr. Bashford Dean (U.S. Fish Commission) gave an account

of oyster-cultural methods, experiments, and new proposals. He pointed out the difficulties in "spat" collecting, and showed that if these could be overcome the problem of raising oysters successfully would be solved. He dwelt on the effects of bad aeration, and of changes of temperature, and on the difficulty in retaining the embryos in closed areas, such as the *mare piccolo* at Taranto and the Brenéguy lake in France. Finally he discussed the cultural methods recently patented in the United States.

Prof. W. A. Herdman and Prof. R. Boyce gave a paper on oysters and typhoid, in which they explained the investigations they had made on the normal and abnormal life-conditions of the oyster, including the effect of pathogenic organisms. The oysters were laid down in various kinds of water, and fed on a variety of substances, both in the laboratories at Liverpool and also at the Port Erin Biological Station. Some of the results obtained are: the beneficial effects of aeration, the superiority of natural food (protophyta, &c.) over artificial (oatmeal, &c.), the deleterious effects of stagnation, great toleration of sewage, inimical effect of typhoid fæcal matter, the identification of *Bacillus typhosus* in oysters fourteen days after infection. The observations are still in progress, and a Committee of the British Association has been formed for the purpose of carrying on the investigation.

Dr. H. C. Sorby read a paper on the oyster culture in the Colne district, which was to be visited by a party of zoologists from the Section the Wednesday following. He described the grounds where spat was obtained, and the celebrated Pyefleet creek where the "natives" are fattened for the market.

Mr. J. T. Cunningham gave the last of the fishery papers, on fish and fishing grounds in the North Sea. This author disputed the idea that the great quantities of young plaice in the eastern parts of the North Sea are derived from the spawn and embryos carried across by currents, and that these plaice when they grow large supply those parts of the North Sea that lie further west. He suggests that the plaice on the German side are a smaller race, and that they correspond in distribution to a tract of warmer Atlantic water. He urged the necessity for a scientific investigation of the North Sea fisheries, and for experiments in rearing young food fish in artificial ponds. A discussion followed, in which the authors of the papers, the President, Mr. Alward, Mr. A. O. Walker, and others took part.

In the afternoon a discussion took place on zoological bibliography, opened by Dr. Haviland Field with an account of his scheme for the establishment of an international bibliographical bureau, to be located at Zurich. The organisation is now nearly completed, and the bureau is expected to start work in January 1896. Dr. Field asks England to form a National Committee, to organise a service of correspondents, and to give a grant towards the Bureau. A Committee of the British Association has been appointed to consider the matter and report.

Dr. Field also read a paper on the date of publication of zoological papers, in which he urged that the date of *distribution* be adopted as "publication."

Rev. T. R. R. Stebbing gave a paper on economy of labour in zoology, proposing that an effort should be made to gather into a succinct form all the most indispensable knowledge in each branch of zoology.

Prof. G. Gilson (Louvain) described the septal organs of *Owenia fusiformis*; Prof. F. Y. Edgeworth read a paper on the statistics of wasps; and Mr. W. Garstang exhibited a simple and efficient collecting reservoir for the surface tow-net. This tow-net was experimented with on Saturday's dredging expedition, and was found to work very satisfactorily.

On Monday forenoon, Prof. L. C. Miall gave an account (illustrated by the lantern) of our present knowledge of the causes and conditions of insect transformation. He pointed out the fundamental distinction between the metamorphoses of insects and those of other animals. The metamorphoses of marine animals were larval, those of insects adult metamorphoses, the migratory stage being late in the life. In insects the migration was undertaken by the adult, the feeding by the young. This caused considerable difference between these two stages, the adult insect becoming more and more highly organised and specialised and the larva more and more degenerate. This marked contrast brought about the necessity for a quiescent pupa stage between. This paper led to some discussion on metamorphosis.

Dr. H. C. Sorby exhibited a series of marine animals caught in the Suffolk estuaries, and mounted as lantern-slides after various methods of preparation.

Dr. Sorby gave an account of his apparatus for catching minute marine animals, and for estimating the number of organisms in given quantities of sea water.

Dr. E. Frankland read a paper on conditions affecting bacterial life in river water, in which he showed that in a series of monthly observations on the water of the Thames bacteria were more numerous in winter than in summer. There were three conditions which might affect the bacteria, and which he had disentangled, viz. temperature, sunshine, and the volume of water. Sunshine was a powerful germicide, but its effect ceases at a small depth in muddy water. The amount of microbes was found to vary with the amount of flood water. Storage has a very beneficial effect in purifying river water from bacteria.

Prof. A. C. Haddon made an appeal to zoologists to urge upon Government and scientific societies the necessity for an immediate exploration of oceanic islands of the Pacific. He pointed out that the great depths of the sea would remain for long unaltered, that the Antarctic was probably not undergoing any rapid change, but that the fauna and flora of the islands, and the customs of their inhabitants, were all undergoing change from year to year, and therefore ought to receive our first attention.

A paper on the Coccidæ of Ceylon, by Mr. E. E. Green, illustrated by beautiful plates, was read by Prof. Howes.

Dr. H. O. Forbes gave a paper, "Criticisms on some points in the summary of the results of the *Challenger* Expedition," in which he dealt with the supposed greater size of the sun in Carboniferous times, and also with the views of Dr. Murray in reference to the occurrence of similar forms in Arctic and Antarctic regions. Finally he pointed out that the evidence for an Antarctic continent in Tertiary times is really supported by the *Challenger* collections, rather than the reverse, as held by Dr. Murray.

A paper on the marine fauna of Houtman's Abrolhos Islands, West Australia, by W. Saville-Kent, showed that the anomalous character of the fauna of Abrolhos can only be accounted for by the assumption that an ocean current setting in from the equatorial Indian Ocean penetrates as far south as this island group.

Dr. Gregg Wilson read a paper on hereditary polydactylism, and also one on the reproduction of the common crab. Dr. Wilson was of opinion that an increased size limit would be a very distinct protection to the crab. A close time at the end of the year would protect the female at a time when there is most destruction.

On Tuesday, Prof. Lloyd Morgan gave an account of his experiments on instinct in young birds. He reared young moorhens, chicks, &c., for the purpose of determining how far the activities of locomotion (swimming, diving, running, flying), feeding, bathing, &c., are instinctive or congenital, and how far their definiteness is a matter of individual acquisition. It was found that timidity had a congenital basis, but was perfected by individual acquisition. There was no instinctive avoidance of insects with warning colours, but such avoidance was rapidly acquired by the individual. There appears to be little support for the view that what is individually acquired is then passed on by heredity.

Dr. Bashford Dean gave an exhibition of ova and larvæ of *Amia*, *Lepidosteus* and *Acipenser*, with some notes on the early development of the Ganoids, in which he brought out that Embryology supports the views derived from Palæontology. Dr. Dean considers that *Lepidosteus* is the oldest or most primitive, and *Amia* the form which comes nearest to the Teleosts.

Dr. Otto Maas (Munich) discussed some questions relating to the morphology and distribution of Medusæ. He exhibited some plates of supposed deep-sea Medusæ from the *Albatross* expedition showing the prevalence of a purplish tint, which he supposed to be the complementary tint to the green phosphorescent light given out by many deep-sea animals.

Mr. J. E. Moore's paper on spermatogenesis in birds, showed that the spermatic elements of pigeons have a marked tendency to form multinucleate masses. The whole course seems to correspond more closely with elasmobranchs than with mammals.

Prof. G. B. Howes read a paper on the mammalian hyoid. He showed that there were two types: (1) Proterostylic, found only in man and marmosets, and (2) Opisthostylic, known only

in rabbits and some other rodents. The following papers: On the development of the teeth in certain Insectivora, by M. F. Woodward; on the poison apparatus of certain snakes, by G. S. West; on the value of myology in the classification of animals, by F. G. Parsons; and on ultimate vital units, by Miss Nina Layard, concluded the ordinary sittings of the Section.

A notable feature of the meeting was the very successful dredging expeditions organised for the Zoological Section by the Local Committee, with the help of the President of the Section and Dr. H. C. Sorby. On Saturday a large steamer was chartered from the Railway Company for dredging outside Harwich. Many hauls of the dredge, and of various forms of tow-net, both surface and bottom, were made off the Naze and in the neighbourhood of the Gunfleet bank. Large quantities of material were obtained, including representatives of most groups of the Invertebrata. The specimens picked out were arranged in a number of large glass jars, and on the return journey Prof. Herdman gave a demonstration on the most interesting forms obtained. On Wednesday, the 18th, the second zoological excursion took place, to Wyvenhoe to inspect the Colne Oyster Fishery, by invitation of the Mayor and Corporation of Colchester. The party were taken on board the new steam oyster dredger of the Fishery Board, and hauls of the dredges were obtained at various points in the estuary of the Colne in order to show the condition of the oyster ground. Large quantities of the Polyzoon *Alcyonidium gelatinosum* and of common Ascidians, especially *Ascidiella virginea*, were found associated with the oysters. The steamer then proceeded to the Pyefleet creek, where three millions of the famous Colchester "natives" are now fattening: here the party landed and inspected the packing sheds, where they were entertained to an oyster luncheon. On returning to the steamer, dredging was again carried on further down the estuary, so as to see as much as possible of the ground, and the different ages and conditions of the oyster. Every facility was given to the party for examining this important fishery, and a most favourable impression was received of the healthiness of the ground, the purity of the water, and the excellent condition of the stock.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THE brilliant International Geographical Congress, recently held in London, seems to have afforded sufficient intellectual dissipation for most British geographers this year, and many familiar faces were absent from Section E. Comparatively few papers were presented for reading, and several of these were read by the Secretaries, as the authors could not attend. It is doubtful whether papers presented in this way should be brought before the Association, for fair discussion is impossible unless the author is present to support his arguments and answer questions.

If Section E retained its usual popularity this year—and the large lecture hall was occasionally crowded—it was not because of the sensational character of the communications made; there was not even a lady-traveller to read a paper. A characteristic of the meeting was the exceptional scientific value of the papers, which dealt less with exploration than with research.

During recent years the President of Section E has almost always been a practical geographer with a commanding knowledge of one branch of his subject, and this year the succession was worthily upheld by Mr. H. J. Mackinder, the Reader in Geography at Oxford, whose experience of higher education in geography enabled him to formulate a scheme for restoring that science to its proper place in a rational university system. The older universities have not responded as was expected to the proposals of the Royal Geographical Society as to the institution of Chairs of Geography, and the time seems to have come for the Society to take a fresh departure, either independently or in conjunction with a new university not blind to the value of the experiment which has been tried and found satisfactory in Germany. A Committee of the British Association has been appointed, without a grant, to investigate the teaching of geography in this country, Mr. Mackinder being chairman and Mr. Herbertson secretary.

The President's contention that geography is not "the science of all things," but a correlating study dealing with the results of all sciences relating to the earth from a special standpoint, was driven home by many of the papers presented to the meeting.

Mr. W. B. Blaikie demonstrated by his greatly-improved cosmosphere the astronomical relations of geography, the combination of a terrestrial globe with a transparent celestial globe on which the constellations are printed, forming a great advance on the old armillary sphere; while the ingenious device of removing a celestial and terrestrial hemisphere allowed of the working of plane problems on the section as readily as of spherical problems on the surface of the outer sphere.

Climatology was discussed in the report of the Committee on the climate of tropical Africa, which was presented by Mr. Ravenstein, the chairman. It shows the results already obtained from the six stations in tropical Africa equipped by the Association. The Committee was reappointed with a small grant and with a change of secretary, Mr. H. N. Dickson taking the place of Dr. H. R. Mill.

Dr. John Murray gave a sketch of the central problem of oceanography—the circulation of the oceans; and the Section instructed the President to write a letter to Dr. Murray, congratulating him on the completion of the *Challenger* Reports, the most important contribution to physical geography of recent years.

Mr. H. N. Dickson summarised the result of the recent international observations on the North Atlantic, in which he took part, and by the aid of lantern diagrams showed that the distribution of the temperature of the surface-water was intimately associated with the distribution of mean atmospheric pressure over the ocean, and that consequently the temperature of the Atlantic water was an important factor in determining the weather as well as the climate of Western Europe.

Mr. A. Trevor Battye read an interesting paper on the struggle for existence in Arctic regions, dealing with biogeographical problems, but unfortunately there was no time to discuss it. A biological discussion which greatly pleased the audience, but was perhaps somewhat inappropriate to the Section, arose on Mr. Borchgrevink's paper describing his recent experiences in the far South, and a proposed plan for a private Antarctic expedition. Sir Joseph Hooker, the veteran of Ross's Antarctic voyages, who was received with great enthusiasm, referred to his adventures in the Antarctic seas, and while congratulating Mr. Borchgrevink on his work in the Norwegian whaling trip, expressed little hope of great results following a private expedition. Sir William Flower had the meeting with him in declaring that no more attempts should be made to send out ships on the pretext of looking for whales or seals, but with the hope of gaining scientific information.

The return to Vardö of the *Windward*, after landing Mr. Jackson in Franz-Josef Land, occurred during the meeting, and Mr. Montefiore, Secretary of the Jackson-Harmsworth expedition, gave a brief account of the start of the land party.

In the historical aspect of geography, Mr. J. L. Myres contributed a discussion of the maps of Herodotus, which enabled an interesting contrast to be drawn between the *à priori* methods of the ancient world and the scientific inductions of to-day.

The papers descriptive of exploration dealt with Africa and Asia. Captain Hinde's experiences in the Congo State, and Mr. G. F. Scott-Elliot's admirable expedition for the scientific study of the Ruwenzori region, have already been before the public in other forms. Mr. H. S. Cowper's journey through Tarhuna and Gharian in Tripoli was new, and the archæological features which he observed seem to be deserving of further study.

The Rev. W. Weston gave one of the most valuable travel-papers—an account of his explorations in the Japanese Alps. This range occupies the centre of the largest island, with summits rising to elevations of over 10,000 feet. The snowfall on the western side is enormous on account of the moisture in the prevailing wind, while the eastern side of the range remains comparatively free of snow. Although the snow-line in summer is as low as 7000 feet in places, there are no signs of glacial action. The volcanic mountains abound in hot mineral springs of high repute as baths, and ores of copper and silver are mined in several places. The flora and fauna are both rich, and the people retain their ancient politeness and hospitality, while many curious customs and beliefs survive amongst them.

Mr. John Dodd, who was not able to be present, sent an exhaustive memoir on Formosa, where he had resided from 1864 to 1890. As a trader he had been much in contact with the aboriginal tribes of the interior, and he gave a graphic account of

their mode of life and their relations with the Chinese colonists. The resources of the island were described, and the prospects of foreign trade discussed. Probably no European is so well able as Mr. Dodd to speak from experience of the latest accession to the empire of Japan.

Dr. A. Markoff drew attention to the geography of Russian Asia, especially with reference to the Siberian railway.

Major Darwin gave an epitome of the work of the sixth International Geographical Congress.

Mr. Miller Christy directed the attention of geographers to the remote islet of Rockall, off the west coast of Scotland, which has never been properly studied, and he suggested that it would be a good field of research for a hardy yachtsman. This paper provoked a lively discussion, in which the value of Rockall as a weather-forecasting station was referred to, and the practical difficulties in the way of utilising it considered.

The Section authorised the President to write a letter of condolence to the parents of the late Mr. Joseph Thomson, expressing the high opinion universally held as to the value of the work he did in Africa, and the warm affection with which his genial personality was regarded by every geographer.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Report just issued by the Somerset County Education Committee shows that the work of technical education is being developed, and mostly in the right direction. Much of the instruction given was of a very elementary character, but this is just what is needed by the type of student for whom it is intended. It is satisfactory to note that a course of experimental science was followed by a number of teachers. The instruction was confined almost entirely to experiments suitable for class demonstration, and, where possible, for repetition by evening school pupils. The words of Mr. C. H. Bothamley, the Director of Technical Instruction in Somerset, as to the use of such practical work, are worth repeating here. "Since the chief object of science teaching in evening schools is not so much to impart a knowledge of useful facts (though that is important), as to train pupils to use their eyes in their daily occupations, to observe accurately, and to reason correctly from what they have observed, it is clear that, if this end is to be attained, the pupils must see things for themselves, and not simply be told things, and the experimental proofs must be complete, and the reasoning based on them must be sound." We will go further and say that the only real scientific knowledge is obtained not from seeing experiments performed, but by doing them. Clear and accurate class demonstrations are undoubtedly good, but practical work carried out by the pupils themselves is far better, and the more facilities that are given for such work, the firmer will be the foundation upon which a superstructure of technical education can be built.

AMONG the recent appointments we notice the following:— Dr. A. Heydweiller, Privat-docent in Physics and Physical Chemistry at Strassburg, to be Extraordinary Professor at Breslau; Dr. Leo Gruenhut to succeed the late Prof. Borgmann at the Fresenius Chemical Laboratory, Wiesbaden; Dr. K. W. v. Dalla-Torre, Privat-docent in Zoology at Innsbruck, to be Extraordinary Professor. Dr. K. Zickler to the full Professorship of Electrotechnology at the Brünn Technical High School, and Dr. Dzieslewski to a similar post in the Technische Hochschule at Lemberg; Dr. E. Yung to succeed the late Carl Vogt as Professor of Comparative Anatomy and Zoology at Geneva; Dr. B. Weinstein to be Extraordinary Professor of Physics in Berlin University; Dr. Max Verworn to be Extraordinary Professor in Physiology at Jena; Dr. Herbert Hurst to be Demonstrator in Zoology, and Mr. Vaughan Jennings to be Demonstrator in Geology, at the Royal College of Science, Dublin; Dr. J. P. Kuenen to the new Harris Chair of Physics in University College, Dundee; Dr. Rawson to be Headmaster of Huddersfield Technical School.

AT the recent Matriculation Examination of the City and Guilds Central Technical College, seventy-six candidates presented themselves, and sixty-two have been admitted to the College. The highest place was taken by M. Solomon, to whom the Clothworkers' Scholarship of £60 a year and free education has been awarded.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 23.—M. Fizeau in the chair.—On a specimen of black diamond from Brazil, by M. Henri Moissan. The specimen is from Bahia Province, and weighs 630 grams (about 3073 carats). Its surface is in part rough, appearing when slightly magnified as if gas had escaped therefrom while in a pasty condition. It resembles the microscopic grains of crystallised carbon produced in the interior of suddenly cooled silver and iron masses. This specimen is porous, and has lost weight since removal from the soil to the extent of sixteen grams.—On the existence of phlorizic glycosuria in dogs after section of the spinal cord, by M. R. Lépine. On the administration of phlorizine, glycosuria follows almost as in the case of healthy dogs, and differs from the latter case merely in the production of a less total quantity of glucose.—A brochure entitled "The actual limits of our science; a presidential address to the British Association at Oxford, delivered August 8, 1894, by the Marquis of Salisbury" (translated by M. W. de Fonvielle), has been printed in the Correspondence of the Academy.—On the composition of pélagéine, by MM. A. B. Griffiths and C. Platt. The violet pigment of the Medusa (*Pelagia*) has the composition $C_{20}H_{17}NO_7$, and is termed by the authors pélagéine. It is soluble in alcohol, ether, and acetic acid, very soluble in carbon disulphide, and insoluble in water. It gives no characteristic absorption bands.

LIEBIG.

Justus von Liebig: his Life and Work (1809–73). By W. A. Shenstone, F.I.C. (London: Cassell and Co., Limited, 1895.)

To those who listened—it is now twenty years ago to the Faraday Lecture given by the late Prof. Hofmann within the walls of the Royal Institution to the Fellows of the Chemical Society of London, or to those who have since read the report of this eloquent and enthusiastic discourse in the *Transactions* of the Chemical Society, the task of preparing a new account of the life and labours of Liebig would appear to be a very difficult one.

But to say merely that Mr. Shenstone has succeeded in this difficult task, would be scarcely to do justice to his admirable little volume, which has evidently been very carefully compiled, and which, while it possesses literary charm of its own, gives a clear and, at the same time, critical summary of the work and writings of the great chemist, which makes it, for popular reading at all events, preferable to Hofmann's brilliant lecture. Mr. Shenstone is evidently a master of exposition, and if in reading through the pages of his book the scientific man encounters one or two statements or expressions of opinion with which he cannot agree, he will be ready to condone these delinquencies in view of the generally excellent style of the whole. And notwithstanding the remark in the preface, that the object has been "not so much to dwell upon Liebig's private life as to tell what he was, what he did, and why all chemists and all those who are versed in the history of science admire and esteem him so greatly," the book, as a biographical sketch, is superior to the lecture. As pointed out by the author, it is quite true, and as remarkable as it is true, that few people nowadays, even among students of chemistry, know much about Liebig's scientific work and his services to the great departments of applied chemistry in physiology, medicine, and agriculture. Liebig's extract of meat, Liebig's potash bulbs, and Liebig's condenser are the only things which a present-day student can usually recall if asked to give an account of Liebig's work, and these he seems generally to regard as trivial inventions deserving of little remark. Liebig's life, cut short, as one would say in these days of general longevity, at the early age of threescore years and ten, was full of activity. The Royal Society Catalogue of Scientific Papers gives a list of upwards of three hundred papers published by him, of which some five-and-twenty were issued under joint authorship with Wöhler, his life-long friend and associate. And the *Annalen*, which to this day are familiarly referred to as "Liebig's," contain in the first 165 volumes issued during his lifetime all the long array of memoirs which embody the results of the researches of the master and his pupils.

Up to the age of sixteen, little promise of future greatness was given by the restless boy, at once "the plague of his teachers and the sorrow of his parents," as he was told by the Rector of the Gymnasium. This period of his life, marked chiefly by conflict with his schoolmasters, reminds one of Darwin's early days at Shrewsbury. And examples of this kind, of which many are now well known, fill one with wonder that the schoolmaster does not yet recognise the need for greater elasticity in the prevalent system of education.

The ideal schoolboy is an orderly machine, always obedient, receptive, submissive, ready in the cricket-field, and with real or simulated enthusiasm for football, despising all other games, and conservative to the backbone. He is the darling of the master, who sends him home with glowing reports and arms-full of prize-books. It seems never to occur to any one that there may be natures to which the classical languages and history make no appeal, who have not the gift of the mathematician, and who do not even care to play at cricket or football. If such appear in a public school they have a bad time of it, dragging out their miserable days at the bottom of the form, regarded as fools by the masters, and as muffs by the boys. And yet among these school failures there may be Liebigs or Darwins, or at any rate there may be, and commonly there is, the material out of which good and useful citizens are made, if only they had a chance to show what they can do.

It is not surprising that Germany should cherish the memory of Liebig, for to his example and influence she undoubtedly owes the development and activity of her chemical schools; and it is interesting to note the relative progress made by the chief European nations in this direction. In Liebig's youth the supremacy of the English and French chemists was unquestioned, Berzelius alone representing the science in Sweden. It was, as Liebig himself says, "a wretched time for chemistry in Germany."

Since that day things have greatly changed, the German laboratories have outnumbered those of England and France together, and their output of scientific results has so greatly exceeded the achievements of all other European countries as to have formed a subject of not undeserved reproach to the rest of them.

At the present time, however, things are not so bad, and there is great hope, from the renewed activity of the universities and technical schools in France and in England, as well as in other parts of Europe and in America during the last few years, that these other countries will in future contribute their full share to the work of experimental investigation and the encouragement of scientific education and thought.

It would be scarcely fair to the author of this "Life" to make any attempt to epitomise it, short and compact as it is. Those who are interested must read the book, and those who read it will certainly be interested. But the estimate formed by the author of the relative value and importance of the several kinds of service rendered by Liebig to the world, seems to be scarcely in agreement with that which is more generally current among chemists and physiologists. First in importance we should place Liebig's work in the domain of organic chemistry. Having shown how to analyse carbon compounds, he led the way in their investigation, and by the introduction of the theory of compound radicles laid the whole foundation of modern organic chemistry. Scarcely second in importance was the establishment of the system of practical teaching in the laboratory at Giessen, which certainly set an example soon followed by all the universities on the

continent, and led to the erection of laboratories in England, not in the great universities, to their shame be it said, but at such places as University College, London, and the College of Chemistry.

Liebig's researches in connection with physiology and agriculture were of the utmost importance in their day, but chiefly by reason of the stimulus afforded to inquiry; for while the whole, or nearly the whole, of his chemical work remains as firmly established as ever, the greater part of his physiological theories in relation to plant nutrition, to fermentation, and to animal physiology, have been either superseded altogether, or so modified as to be no longer recognisable.

The author will probably see fit, on further reflection, to alter some of the views expressed in his own remarks; but enough has been said to show that Mr. Shenstone has made a contribution to the "Century Series" which will, we venture to think, be by no means the least attractive and interesting of these useful little volumes.

W. A. T.

THE SELECTION OF HEALTH RESORTS.

Climates and Baths of Great Britain. Vol. i. (London: Macmillan and Co., 1895.)

THIS work is the outcome of the report of a committee appointed by the Royal Medical and Chirurgical Society of London for the purpose of investigating questions of importance with reference to the climatology and balneology of Great Britain and Ireland.

The information contained in the volume—which deals with the climate of the south of England and with the chief medicinal springs of Great Britain—may be summarised as follows:

(1) Information received from medical practitioners in the districts dealt with.

(2) The results of personal investigations by members of the committee.

(3) The analysis of published vital statistics of the localities in question.

That the treatment of the climatology of very small areas of these islands is a difficult and complex matter, is a fact patent to every one; it is every one's experience, for instance, that one side of a bay or headland, owing to its exposure, may be tonic and bracing, whereas the other side, owing to a different aspect, or to protection by high cliffs and woodland, may be warm and relaxing. But since meteorological data are of undoubted value in determining the suitability of an area for the residence of those suffering from various diseases, it is certain that some measure of the utility of the present work should be gauged from the detail and precision of these data; and the book will be found lacking in this respect. Little blame is attachable, however, to the contributors, who have in the majority of cases made the most of their available information; the fact is, we have not yet at hand sufficient data to enable a scientific work upon the climatic conditions of all the many small areas here dealt with to be penned; the records are so few, that it is very frequently found necessary to supplement instrumental observations by personal impressions. Thus we are constantly told that one place is *probably* colder than another, that it is thought to have more mist and moisture in the atmosphere, and so on; and one so frequently encounters such remarks as "there are no climatic records, but the impression is," &c., that the conviction is more and more borne home that it would have been well if the committee had first taken some steps, through medical men and others, to secure more scientific data before publishing the present volume. With rare exceptions, precise meteorological data are confined to towns and their immediate neighbourhood; and to show the difficulty with which the committee had to contend in the case of one important county (*i.e.* Somerset), it is sufficient to state that this county possesses at the present time only one station of the Royal Meteorological Society.

Then, again, atmospheric conditions and health are so largely the outcome of geological factors, that in a few instances it is matter for regret that this subject is not treated with a little more fulness; and in such a work one would expect to find some observations upon the mean height, and the extent of variation from the mean, in the ground-water level, knowing as we do the important bearing which this has upon health and disease.

So far as the information relates to the healthiness of the various areas treated of, and their suitability for residence by patients suffering from various diseases, much will be found of real value: but here again the contributors have had to face great difficulties—difficulties which in many respects are practically insurmountable; and here again the work presents some shortcomings. In making deductions from vital statistics, it would have been better and safer to have done so from as many returns as possible, and not to have rested satisfied, as in so many instances, with the actual records of just one brief year; and it would, moreover, have been more serviceable to those who would like to make their own deductions as to the relative advantages of different areas, if instead of the actual number of deaths being given, the rates of the more important diseases had been worked out for each locality. As it is, it would be a matter of no small labour to decide which of the many areas dealt with stands best with regard to *relative* immunity from any particular disease.

In the reports of local practitioners there is occasionally some evidence of the touch of a loving hand, the attractions and healthiness of the part being enthusiastically attested to; and for this reason, again, it will be no easy matter to conclude, from a perusal of the work, as to which is the most desirable spot to select; but at least one is not likely to fix upon Dartmoor, which an informant asserts has on an average 319 wet days in the year. Most of this local information, however, is very fair and impartial, and the conscientious and judicial manner in which conclusions are drawn by the different authors from the information at their hands is a striking feature of the work.

The committee points out that in a work comprising information of many sorts and from many sources, it is inevitable that a certain amount of error must have crept in; but as a matter of fact, the reader will discover scarcely any error of commission; what blemishes the work possesses are undoubtedly on the score of omission. There is one glaring instance of contradiction which we have noticed, and which will serve to present a good example, to the lay mind, of how doctors disagree. On

p. 38 we read. "The influence of sea air in causing anaemia is apparent on many parts of the coast," and on p. 47, "It may be stated that the infrequency of anaemia in the local inhabitants is no doubt due to their proximity to the Atlantic."

To instance the difficulty, which frequently presents itself, of arriving at just conclusions from the statistical information acquired by the committee, let us ask ourselves what inference may justly be drawn when the phthisis rate is high in certain health resorts. It is very properly pointed out that much of this excess is doubtless due to phthisical immigrants to a spot which is known to be congenial to phthisical patients. Quite true! But if we cannot ascertain *to what extent* the rate is influenced by phthisical immigration, how is one to know whether the local conditions, *per se*, are favourable or not to the disease in question? It is conceivable, in this relation, that certain limited areas of England with comparatively mild and equitable climates have now a native population strongly predisposed to phthisis from the fact that their ancestors were originally phthisical immigrants attracted to the spot; so that even if it were practicable that the vital statistics of visitors could be separately compiled, the local and climatic advantages or disadvantages of the area in respect of this disease could never be put upon a scientific basis from vital returns alone. It is well known, moreover, that deductions drawn from meteorological data on the score of the suitability of the various areas for the residence of those suffering from different diseases, must be made with many reservations, that the subject does not admit of generalisations; for, *inter alia*, the suitability of the climates of certain health resorts for different patients is governed to such an extent by that wonderful personal factor that makes the same spot bracing to one and relaxing to another, benevolent to a certain disease in one and malignant to that disease in another, that frequently the individual can only arrive at the conclusion as to which area suits him best by an actual personal experiment. And thus it comes about that perhaps, after all, the surest lines upon which a physician can act, are in the main empirical as to his patient. We have lived long enough in these islands to know by experience which are the warmest, driest, and most sheltered spots, which are the dampest, and which are the most bracing and relaxing, and it is quite a question whether meteorological data will help the physician much farther. He will generally select for his patient what has been proved by the experience of many generations to be a congenial site, and nothing short of a cautious experiment with the patient himself will suffice to tell him which of several alternative sites suits his patient best; but to this end the experiences and views of other practicising physicians would be of immense value, and one is tempted to ask whether a work embodying and summarising as many as possible of these experiences would not serve even a more useful purpose than the first 500 pages of this book.

The chapters dealing with the medicinal waters of Great Britain are well written, useful, concise and impartial.

The committee hopes to deal in a further report with the climatology of the remaining districts, and with those mineral springs which are not included in the present volume.

OUR BOOK SHELF.

Abrégé de la Théorie des Fonctions Elliptiques. Par Charles Henry. 124 pp. (Paris: Nony, 1895.)

AN introductory course of elliptic functions, intended for those who have a fair acquaintance with integral calculus, should consist of three stages. In the first stage the subject would be approached as a development of integral calculus, the addition theorem and periodicity obtained, and a large number of applications made to problems whose solutions can be expressed in the notation of elliptic functions. Difficulties of the multiple interpretation of the square roots of variable functions would be pointed out, and left. In the second stage an elementary introduction to the modern descriptive theory of functions of a complex variable would be furnished, containing a fairly full account of the theory of doubly periodic functions, illustrated at every stage by examples from the functions whose existence has been foreshadowed in the first stage. The third stage would be a systematic development of the elliptic functions, with the help of the elementary theory of functions, finishing, not beginning, with the differential equation and the applications to integral calculus. Such a course would require at least twenty-five hour-lectures, and the unfamiliar character of the second and third stages would make a careful revision necessary.

The present little volume is concerned with the third stage; on the whole, there can be no doubt that it is the most suitable handbook which has yet appeared for the use of teachers engaged in such a course as sketched above. The elliptic functions are obtained by the infinite double series for $\wp'(u)$; and certainly the idea is the right one, though it is easier to begin with the series for $\wp'(u)$. The differential equation is hence obtained, and the following chapter attempts to establish the functions on that basis. It seems preferable that this should be postponed, and treated only by Riemann's methods. Chapters iii. and iv. introduce the functions ζu and σu, as is quite proper; but it would seem much better that the addition equation, obtained in chapter v., should be obtained independently of the σ functions, and by Abel's method, with the help of a plane cubic curve. The functions $\sigma_1(u)$, $\sigma_2(u)$, $\sigma_3(u)$, are then obtained, and hence it is proved that the functions $\sqrt{\wp u - e_1}, \ldots$ are single-valued functions of u. It is a distinct step in the right direction to make the statement that these functions $\sqrt{\wp u - e_1}, \ldots$ are single-valued; but the fact ought to be obtained before, and independently of, the investigation of their actual values. The same remark holds in regard to the functions $cn\, u$, $dn\, u$: if $x = sn\, u$, it ought to be shown that $\sqrt{1-x^2}$ is single-valued before its actual value is obtained, and the remark emphasised by proving that such a function as $\sqrt{(1 - sn\, u)(1 - k\, sn\, u)}$ is equally a single-valued function of u. The fact, which is obtained, that all doubly periodic functions are rationally expressible by $\wp u$ and $\wp' u$, ought to be compared with the fact that all doubly periodic functions are rationally expressible by $sn\, u$ and $cn\, u\, dn\, u$; and it ought to be clearly seen that when we are dealing with Jacobi's functions, $cn\, u$ is no more a function of the same kind as $sn\, u$ than is $\sqrt{\wp u - e_1}$ of the same kind as $\wp u$ when we are dealing with Weierstrass's functions. In these two cases respectively, $cn\, u$ and $\sqrt{\wp u - e_1}$ are *factorial* functions, which ought to be carefully distinguished from the two fundamental functions whereby the algebraical irrationality under consideration is resolved.

With these criticisms, and the remark that the accounts of the transformation and of Jacobi's θ functions are not so full as one desires, we may conclude, strongly recommending all who desire a useful class book, to which, however, many explanations and illustrative examples must be supplied, to adopt the book. H. F. BAKER.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Clausius' Virial Theorem.

THE question raised by Colonel Basevi, in NATURE for August 29, illustrates the importance of keeping in view a clear statement of what a general theorem such as that of Clausius with respect to the *virial* asserts, and the essential relativity of the forces which are regarded as acting on the particles, and of the kinetic energy of the system. The theorem asserts, I think, that if the motion of the system of particles be continued over any interval of time, t_1, the excess of the mean value of the kinetic energy of the system for that interval of time over the virial for the same interval is equal to the excess of the value of $\frac{1}{4t_1}\Sigma m\frac{d(\rho^2)}{dt}$ at the end of the interval over its value at the beginning, ρ being the distance of a specimen particle from the origin and m its mass, and the summation being extended over all the particles of the system.

It may be noticed here that the mean value of the kinetic energy of a system for an interval of time t_1 is equal to the *action* of the system for that interval taken per unit of the time in the interval.

There can be no doubt that the theorem is true, and will be verified by any test case to which it can be applied. The proof given by Clausius himself is perhaps the simplest, but the following mode of arriving at the theorem is instructive in some ways. Refer the particles to a system of rectangular axes in the ordinary way, and adopt the fluxional notation for velocities and accelerations. Thus taking a specimen particle, which is at the point x, y, z, at time t, regarding, as we are at liberty to do, the velocities $\dot{x}, \dot{y}, \dot{z}$, as functions of the position of the particle in the motion, we have

$$m\left(\dot{x}\frac{\partial\dot{x}}{\partial x} + \dot{y}\frac{\partial\dot{x}}{\partial y} + \dot{z}\frac{\partial\dot{x}}{\partial z}\right) = m\ddot{x} = \mathrm{X}$$

and two other equations for Y, Z, which can be written down from this by symmetry. Multiplying these equations by x, y, z respectively, adding, and rearranging, we easily find

$$\frac{m}{2}\left(\dot{x}^2 + \dot{y}^2 + \dot{z}^2\right)dt = -\tfrac{1}{2}\left(\mathrm{X}x + \mathrm{Y}y + \mathrm{Z}z\right)dt + \frac{m}{2}d\left(x\dot{x} + y\dot{y} + z\dot{z}\right).$$

Integrated from $t = 0$ to $t = t_1$, and extended to all the particles, this gives

$$\tfrac{1}{2}\Sigma m\int_0^{t_1}(\dot{x}^2 + \dot{y}^2 + \dot{z}^2)dt = -\tfrac{1}{2}\Sigma\int_0^{t_1}(\mathrm{X}x + \mathrm{Y}y + \mathrm{Z}z)dt + \tfrac{1}{2}\Big[\Sigma m(x\dot{x} + y\dot{y} + z\dot{z})\Big]_0^{t_1}.$$

The expression on the left [which may be written

$$\Sigma m\int(\dot{x}dx + \dot{y}dy + \dot{z}dz)]$$

is nowhere asserted, so far as I know, to be kinetic energy, but is the time integral of the kinetic energy (that is the *action* of the system) for the time-interval t_1. Dividing both sides by t_1 we get the theorem as stated above, namely

$$\frac{1}{t_1}\int_0^{t_1}\mathrm{T}\,dt = -\frac{1}{2t_1}\Sigma\int_0^{t_1}(\mathrm{X}x + \mathrm{Y}y + \mathrm{Z}z)dt + \frac{1}{4t_1}\Big[\Sigma m\frac{d}{dt}(x^2 + y^2 + z^2)\Big]_0^{t_1},$$

where T denotes the kinetic energy of the system at the instant t.

It is clear that if t_1 be taken very great, and the velocity and the distance of each particle from the origin be always finite, the term on the left is neither infinite nor zero, while the last term on the right becomes vanishingly small. This is Clausius' case of "stationary motion", in which it is justifiable to write

$$\frac{1}{t_1}\int_0^{t_1}\mathrm{T}dt = -\frac{1}{2t_1}\Sigma\int_0^{t_1}(\mathrm{X}x + \mathrm{Y}y + \mathrm{Z}z)dt.$$

The expression on the right is the *virial*, and is in the circumstances stated undoubtedly equal to the time average or mean value of the kinetic energy, as the equation asserts.

If R be the force acting on a particle in the direction *towards* the origin along the line joining the origin with the particle, and ρ the distance of the particle from the origin, we have

$$\mathrm{X}x + \mathrm{Y}y + \mathrm{Z}z = -\mathrm{R}\rho,$$

and the theorem for stationary motion may be stated thus,

Mean value of T = mean value of $\tfrac{1}{2}\Sigma\mathrm{R}\rho$,

where the summation takes in each particle once, and once only.

Let us apply this to the case taken by Lord Rayleigh, and alleged by Colonel Basevi to contradict the theory, of two particles each of mass m, at a distance apart $r (= 2\rho)$, revolving round their common centre of gravity. Here, taking the origin at the common centre of gravity, we have constant values of the virial and of T, namely $\tfrac{1}{2}\Sigma\mathrm{R}\rho = \mathrm{R}\rho$ and $\mathrm{T} = m\mathrm{V}^2$. Thus, $m\mathrm{V}^2/\rho = \mathrm{R}$, which, as Lord Rayleigh remarks, agrees with the law of centrifugal force.

If we take the motion relatively to one of the two particles regarded as at rest, we get the same result. The relative velocity of the other particle becomes $2\mathrm{V}$, and the corresponding kinetic energy $2m\mathrm{V}^2$, the distance of the origin from the other particle 2ρ, and from itself zero. Since the acceleration of the moving particle relatively to the particle now supposed reduced to rest, is double its acceleration relatively to the common centre of gravity, the force now considered as acting on the moving particle must be taken as 2R. Thus we have $2m\mathrm{V}^2 = \tfrac{1}{2}2\mathrm{R} \times 2\rho$, or as before, $m\mathrm{V}^2/\rho = \mathrm{R}$.

If we do not suppose the origin to coincide with one of the particles reduced to rest in this manner, but to coincide for the moment with the *position* of one of the particles, the velocity of each particle is V, the force towards the origin on that distant from it r is R, and we have $\mathrm{T} = m\mathrm{V}^2$, $\tfrac{1}{2}\Sigma\mathrm{R}\rho = \tfrac{1}{2}\mathrm{R}r$, since now $\rho = r$. Hence once more $m\mathrm{V}^2/\rho = \mathrm{R}$.

Similarly, any other origin and axes of reference would give the same result. Colonel Basevi has, it seems to me, overlooked the fact that in the theorem it is the forces acting on each particle relatively to the assumed axes, and the corresponding motions that must be taken into account, and that in the case of a system of particles between which exist forces of mutual attraction, the stress between a given pair can only enter once into the value of $\tfrac{1}{2}\Sigma\mathrm{R}r$.

A. GRAY.

Bangor, September 1.

I THINK the fort will not surrender at Colonel Basevi's summons. We have

$$m\frac{d}{dt}\left(x\frac{dx}{dt}\right) = mx\frac{d^2x}{dt^2} + m\left(\frac{dx}{dt}\right)^2;$$

and if we put $x = u$ and $\frac{dx}{dt} = v$, this may be written

$$m\frac{d}{dt}(uv) = mu\frac{dv}{dt} + mv\frac{du}{dt}$$

and

$$(uv)_t - (uv)_0 = \int_0^t u\frac{dv}{dt}dt + \int_0^t v\frac{du}{dt}dt = \int_0^t udv + \int_0^t vdu,$$

if you please so to write it. This corresponds to Colonel Basevi's equation, except that I have written v for his $\dot{x}$.

But now $m\int vdu$, or $m\int v\frac{du}{dt}dt$, *does* represent kinetic energy.

And $-m\int_0^t udv$ or $-m\int_0^t x\frac{d^2x}{dt^2}dt$ is the virial. The equation shows that if for a certain time t, the right-hand member, vanishes, then on the average of that time t, the two terms on the right are equal and opposite.

The form $\Sigma\mathrm{R}r$ is a rather slippery one. If in the example which Colonel Basevi quotes from Lord Rayleigh, you put $\mathrm{X}x + \mathrm{Y}y$ for $\mathrm{R}r$, it comes out easily. For we may take for origin the centre of the circle of radius ρ. Then

$$\mathrm{X} = \frac{x}{\rho}f, \quad \mathrm{Y} = \frac{y}{\rho}f \text{ and } \mathrm{X}x + \mathrm{Y}y = f\rho.$$

And therefore

$$\Sigma\tfrac{1}{2}mv^2 = \Sigma\tfrac{1}{2}mf\rho,$$

or

$$f = \frac{v^2}{\rho}.$$

S. H. BURBURY.

COLONEL BASEVI'S criticisms of Clausius' virial theorem are not justifiable.

In the first place, the left-hand side of his equation at the foot of p. 413 should be $ux - [ux]_{t=0}$, since the latter term is not necessarily zero even for periodic motion: *e.g.* it equals 1 if $x = \exp. (\sin t)$.

In the next place, though this difference obviously vanishes for periodic motion when the "suitable value given to t" is a multiple of the period, yet for this *same* value of t the areas $\int u dx$ and $\int x du$ will *not* vanish; indeed for *no* value of t can the former vanish, as it represents $\int (dx/dt)^2 dt$, which is the sum of essentially positive quantities. Hence we can have but $\int u dx = - \int x du$ when $xu = [xu]_{t=0}$.

Thirdly, though in the case of stationary motion the areas $\int u dx$ and $- \int x du$ may not be exactly equal for any value of t, yet their difference can only fluctuate within certain narrow limits, so that when multiplied by $m/2t$ it becomes vanishingly small if t is large enough, which is all that Clausius asserts.

Fourthly, Clausius does *not* take $m \int u dx$ to represent kinetic energy, but this expression divided by $2t$.

Fifthly, the fact is overlooked that R refers, not to single particles, but to *pairs* of particles; so that in Lord Rayleigh's case, $\frac{1}{2}\Sigma \mathrm{R}r = \frac{1}{2}\mathrm{R}r$, and not $\mathrm{R}r$, as asserted, there being only *one* pair of particles in question, and the virial equation *does* therefore give $\mathrm{R} = mv^2/\rho$, the ordinary law of force for uniform circular motion.

Lastly, there is no ground whatever for taking $\frac{3}{2}\mathrm{V}r$ and $\frac{1}{2}\Sigma \mathrm{R}r$ as equal terms, there being absolutely no connection between them except that both represent energy; indeed, by this assumption Colonel Basevi obtains a formula which gives for the pressure in an ideal gas only half its proper value.

Hutton's "Theory of the Earth."

IT is to be doubted whether any work, with the exception of Lyell's "Principles," has had a more important influence on the science of geology than Hutton's "Theory of the Earth," in which for the first time the true mode of studying the science was set forth and its fundamental facts outlined.

The theory was first propounded in a paper of some ninety-five pages, written in 1785, which appeared in 1788 in the first volume of the *Transactions* of the Royal Society of Edinburgh, and was at once attacked by a number of hostile critics.

Ten years later, in 1795, it was republished in Edinburgh, greatly extended, and including the results of much additional work, in two good-sized octavo volumes. These included the substance of a number of papers published by Hutton after the appearance of the first outline, as well as answers to his various critics, and is the work which has become a classic in the science.

The work, however, in its published form is evidently incomplete, for on the title-page it is stated to consist of four parts, and, in the table of contents, volume i. is called part i. and volume ii. part ii. Volume ii., furthermore, concludes abruptly with the following words: "Therefore in pursuing this object. I am next to examine facts, with regard to the mineral part of the theory . . . and endeavour to answer objections or solve difficulties which may naturally occur from the consideration of particular appearances."

Parts iii. and iv., so far as I can ascertain, if written, were never published. In the library of the Geological Society of London, however, there is a manuscript of Hutton's which is apparently a portion of one or other of these parts. It is bound in book form, and was presented to the library by Leonhard Horner, Esq., and in a note by that gentleman, presenting it to the Society, it is stated to be one of a series, and to have been given by Dr. Playfair, the populariser of Hutton's work, to Lord Webb Seymour, and on the death of this nobleman to have passed to the Duke of Somerset, who gave it to Mr. Horner. It bears no title, and consists of six chapters numbered from iv. to ix., and was evidently continued in another manuscript, as the last page, forming the conclusion of chapter ix., bears the words "chapter x." at the lower corner.

The manuscript treats chiefly of a subject the investigation of which has been so prolific of results in recent years, namely granite contacts, and especially the contact of granite masses with "schistus." He shows that the granite was not a "primitive" rock on which the schist was deposited, but that it was intruded through the latter in a molten condition, and holds that it was the agent by which mountain-chains were upheaved, supporting his proposition by a description of the relations of these rocks in various parts of Scotland and elsewhere, among them the Island of Arran. To the description of this last-mentioned locality a whole chapter is devoted, in which the true nature of the pitch-stones is also set forth, and the derivation of the felsites from them by a process of dentrification is recognised.

It is merely desired in the present letter to draw attention to the fact that at least some other volumes of this manuscript are extant, and to urge upon those who may know where they might be sought, or who may by chance come upon them, the importance of preserving them, and of placing them, if not in the Geological Society's library with the fragment above referred to, at least in some library where they may be at once secure and available for use.

The book is one of the most remarkable which has appeared in the history of geological science, and all who are interested in the science must desire to see it secured and preserved in its completed form. FRANK D. ADAMS.

McGill University, Montreal.

Abnormal Atlantic Waves.

IT happens that I have only quite lately seen a letter on this subject in NATURE of March 7, from Mr. E. C. Stromeyer of Glasgow. It may perhaps be of interest to some of your readers to learn that on January 6, 1891, and about 4 p.m., the people of Funchal, the chief town of Madeira, and situate on the south coast (lat. 32° 37′ 45″ N., long. 16° 55′ 20″ W.) were astonished by the arrival of a great wave which burst with violence on the shore, coming seemingly from the S.E. or E.S.E. The sea had been calm previously, and the wind was light. At Machico, a village some fifteen miles to the east of Funchal, a similar phenomenon took place contemporaneously, and also at Camara de Lobos, a village about six miles to the west. At the latter place, where there is a small bay amongst the rocks, there were three risings of the sea, one much higher than the others. The bottom of the bay was laid bare, and fishes were seen struggling in the mud. The boats lying on the beach were more or less damaged, but I did not hear that other property was injured.

Two electric cables belonging to the Brazilian Submarine Telegraph Company connect Funchal with Lisbon. Now, it is worth noting that early on the morning after the occurrence of the great wave, when the Company's officials stationed at Funchal went as usual to test the cables, one of them was found to be broken in deep water at a distance of seventeen or eighteen miles to the south of Madeira, whilst the other cable was in good working order. It is an unsolved question whether the same cause that produced the great wave had also broken the cable, or whether the two events were simply coincident but due to independent causes.

Slight shocks of earthquake are felt at distant intervals at Madeira, but no seismic disturbance was noticed near the date of the great wave.

As the wave came from the southwards, I asked a friend to make inquiry at Tenerife whether anything of the sort had been experienced there. The reply was that nothing extraordinary had occurred on January 6 at Santa Cruz on the south coast of that island. At Puerto Orotava, on the north coast, there was bright weather at the time, with light winds, and no wave had occurred, nor had any earthquake been felt.

JAMES YATE JOHNSON.

Funchal, Madeira, September 17.

Leaf-absorption.

A FEW weeks ago I threw some cuttings of the common Privet (*Ligustrum vulgare*) on the borders in the garden. Of these cuttings some perished, while the remainder were drawn into the soil by the worms, some with the cut end downwards, some only by a single leaf, leaving all the rest of the cutting *en*

... *air*. These latter are, at the end of this time, all as fresh and healthily green as they were at the moment of cutting off the parent plant, notwithstanding the very hot weather we have recently experienced. It seems to me that this is a clear proof that the *rôle* of leaves is to *absorb* as well as *evaporate*, a point on which much doubt has often been expressed. G. PAUL.

Harrogate, September 29.

IT has been proved over and over again, and it is easy to prove, that the leaves of some plants, though probably not of all, are capable, under certain conditions—usually abnormal conditions—of absorbing aqueous vapour or fluid water; but this action can hardly be regarded as a function, though I am not prepared to say that absorption of moisture by leaves is in no case a part of the every-day life of a plant. The return to turgidity of the leaves of a plant during the night is, however, in a general way, due, doubtless, to reduced transpiration, rather than absorption from the atmosphere. Yet in the absence of a counteracting current of water from the roots, the leaves of some plants, especially of those inhabiting almost rainless regions, but where the air sometimes reaches almost complete saturation, absorb moisture. At least, so it is asserted. With regard to absorption by detached leaves, or by leaves of detached branches, the development of the action depends, apart from other circumstances, on the amount of vital energy left; and this is determined, to a great extent, by age. The common Privet is a shrub of extraordinary vitality, rare in our native vegetation. I hardly need add that proof of leaves being able to absorb water may be had by inserting withered leaves in water by their upper halves, leaving the stalk out. If not too old, or too much dried, the whole leaves will regain turgidity, though the process may be a slow one.

W. BOTTING HEMSLEY.

Tertiary Fossil Ants in the Isle of Wight.

IN a paper published in NATURE for August 22, p. 399, by Prof. C. Emery, on "The Origin of European and North American Ants," the author states that "the Sicilian amber of Miocene age contains genera which belong to the actual Indian and Australian fauna, while the Baltic amber contains the genera Formica, Lasius, and Myrmica." In the Bembridge limestone in the Isle of Wight, of Eocene age, the same as the Baltic amber, the following genera occur: Formica, Myrmica, and Camponotus, and some others not yet described. In my collection there are a large number of these Hymenoptera, generally well preserved, and seem to be more numerous than any of the other insects from the same beds. It is only of late years that any number of insects have been met with in the British tertiaries, and it is well to record the two genera referred to Formica and Myrmica, being found both in the Baltic amber and Bembridge limestone. Among the numerous fossil insects in my possession from the Lias, no trace of any ants has been observed, and it seems that they did not come into existence until the later Tertiary epoch.

P. B. BRODIE.

THE NORMAL SCHOOL AT PARIS.

IN connection with the celebrations of the centenary of the foundation of the École Normale in Paris, referred to at the time in these columns (vol. lii. p. 613), a ponderous tome has been published[1] containing the complete history of the school, and details concerning the most renowned of its alumni. Opportunity is thus afforded of giving a sketch of the development of a school which has played an important part in the history of education for nearly a century, and which has been the [illegible] college of many of the most distinguished Professors in France.

The most elaborate article in the volume is a detailed history, by M. Paul Dupuy, on "L'École Normale de l'an III." This article has furnished the particulars with reference to the early history of the school given in this contribution.

When the Convention of the 9th Brumaire, An. III. (October 30, 1794), passed the decree to which the Normal School owes its foundation, it realised an idea which had occupied the attention of the University and Parliament for many years. So far back as 1645 the University of Paris considered a proposal by the rector, Dumonstier, to provide the means for the education of teachers and principals. After the expulsion of the Jesuits in 1761, the Parliament of Paris began to carry out the idea by instituting fellowships and uniting at Louis-le-Grand the scholars of the small colleges of the University. At the time when Parliament was taking these steps, Barletti de Saint-Paul was forming a training school for teachers, in which his principles of personal pedagogy were taught; and Bernardin de Saint-Pierre pleaded for a college of instruction. "J'admire avec étonnement," he wrote in 1789, "que tous les arts ont parmi nous leur apprentissage, excepté le plus difficile de tous, celui de former les hommes." To the influence which these educational reformers had in bringing the matter before the Government of the Revolution must be added the impulse derived from Germany, through Alsace. Alsace was then the only province of France able to furnish ideas and models for popular instruction. It had been touched by the great pedagogic movement in Germany, and its great influence upon the three Revolutionary Assemblies makes it prominent in the history of the Normal School.

Practically every part of the educational system of France owes its development to the Republic. The Committee of Public Welfare early concerned itself with the question of national education, and Commissions were appointed to report upon the best means for developing an educational system. In 1793 a plan was put forward to establish normal schools for the training of teachers. Nothing definite was formulated, however, with reference to the Normal School until September 1794, when the Committee of Public Instruction adopted a series of articles, the first of which was to the effect that "there should be established, at Paris, a Normal School, where instruction in the art of teaching science should be given to persons already possessing scientific knowledge." At the end of the following month, the National Convention, after a discussion of the scheme and the subjects to be taught, passed a law for the establishment of Écoles normales. The idea was to establish these schools in various parts of France, but it was not then realised, and the Normal School at Paris is the only one that owes its existence directly to the law of the Convention. Referring to the designation of the schools, an official note reads: "The word *normal*, which has been applied to the schools newly decreed, is taken from geometry. It expresses really the perpendicular or level. In the sense employed in this case it announces that all knowledge belonging to science, to the arts, to belles-lettres, &c., will there be taught, and taught to all equally." Science was thus placed upon the same footing as the humanities. The methods and results of investigation were not to be known to a few, but were to be taught by the most eminent men it was possible to obtain. The first programme of the courses and professors shows the scope of the instruction given.

Subjects.	Professors.
Mathematics	Lagrange and Laplace.
Physics	Haüy.
Descriptive Geometry	Monge.
Natural History	Daubenton.
Chemistry	Berthollet.
Agriculture	Thouin.
Geography	Buache and Mentelle.
History	Volney.
Morals	Bernardin de St. Pierre.
Grammar	Sicard.
Analysis of the Understanding	Garat.
Literature	La Harpe.

A glance at this list will show that the professors were selected on account of their eminence in different

[1] [illegible] (Paris: [illegible])

branches of knowledge rather than for purely pedagogic ability, though the object for which the school was founded was to instruct teachers in the principles of their profession. Berthollet was the only one of the professors of science who paid any serious attention to that subject in the official programme issued to the students; his colleagues confined themselves to purely scientific matters. Methods of research appear to have formed the subjects of the lectures rather than methods of exposition and education; Lagrange and Laplace made this plain in the following announcement of their courses: "To present the most important discoveries that have been made in the domain of science, to develop the principles underlying them; to notice the acute and valuable ideas which gave birth to them; to indicate the most direct road to discovery, and the best sources where details can be obtained; to show what is still to be done, and the steps it is necessary to take; these are the objects of the Normal School, and it is from this point of view that mathematics will be taught."

On January 21, 1795, the lectures commenced at the Museum d'histoire naturelle, the amphitheatre of which had just been completed, and which was given up provisionally to the Normal School. In the presence of a large assembly, Lakanal read the decree establishing the school, and was followed by Laplace, Haüy, and Monge, each of whom read their programmes, and indicated the lines they intended to follow. But the excited state of France during this period was such that the students could not be properly disciplined. Political petitions and manifestos frequently emanated from the school, and there appears to have been an almost entire want of organisation. The excessive petulance of the students showed itself during the lectures, and especially in debates after the lectures, the subjects of which were freely discussed and criticised, to the frequent embarrassment of the professors. Eventually the debates were suppressed in the case of the science lectures. Haüy substituted the debates by laboratory work, and the professors of mathematics instituted debating societies to be managed entirely by the students, who were to mutually assist one another. These conferences were only organised for mathematics, and they appear to have been installed at the College de France, where they were held every day. The "conference" system of education is a legacy from the Normal School of the year III. of the National Convention; to that school is also largely due the place which science now occupies in the French system of education; letters and science were taught by men of equal high rank and authority, and the students selected either branch of knowledge, according to their inclinations and natural gifts. The students at the school were drawn from all parts of France, and maintained by the Republic. But the national exchequer at the time could not stand any extra drain upon its impoverished resources. It is, therefore, no matter of surprise that when the courses ended in May 1795, the school was closed.

In spite of its imperfections, the School of the Convention exerted great and beneficial influence upon the French nation. Biot, in his history of science during the French Revolution, compares the school to a "vast luminous column which rose so high from the middle of a desolate land that its great brilliancy covered France and enlightened the future." And, speaking at the Paris Academy of Sciences in 1833, Arago said, with reference to the school, "It was always necessary to go back to the École normale to find the first public instruction in descriptive geometry. From that school the instruction passed, almost without modifications, to the École polytechnique. From the École normale also dates a veritable revolution in the study of pure mathematics. The demonstrations, methods, and important theories hidden in academic collections, were for the first time presented to students, and encouraged them to rebuild, on new bases, the works intended for education." Arago thus showed that, through the Normal School, science gained the right of an important place in public education. He insisted upon another point none the less important, viz. that at the Normal School, for the first time, at least officially, public education was given by the first men of intellect in the country. "With some rare exceptions, scientific investigators at one time formed in France a class totally distinct from that of the professors. By bringing the first geometers, the first physicists, the first naturalists into the professoriate, the Convention endowed the educational functions with unusual advantages, the fortunate results of which are still felt. In the eyes of the public, the school that bore the names of Lagrange, Laplace, Monge, and Berthollet could claim equality with the highest places of instruction." The first Normal School, in fact, in spite of its brief existence, founded a tradition which was preserved during the Restoration, and under the second Empire, and which has had a decisive influence upon the history of education in France. For this reason, M. Dupuy is justified in concluding his detailed history of the School of the Convention with the words: "The centenary that the École normale has celebrated this year is therefore more than the centenary of its name; it is that of the institution itself under its first form."

The second stage in the history of the Normal School began in 1808 (that is, four years after Napoleon had changed France into an Empire), with an Imperial decree establishing "un pensionnat normal, destiné à recevoir jusqu'à trois cents jeunes gens qui y seront formés à l'art d'enseigner les lettres et les sciences." This decree extending the organisation of the French University, created two years before, founded definitely the present school. Before students were permitted to enter the school, they had to agree to remain in the teaching profession at least ten years. They attended classes at the Collège de France, the École polytechnique, and the Museum d'histoire naturelle, according to whether they intended to instruct in letters, or in different branches of science. An annual grant of three hundred thousand francs (£12,000) was voted for the expenses of the school. The regulations were based upon those of the colleges of the old university, so the students were prevented from taking part in the affairs of the political world. This organisation, however, did not last long; for in 1814 there came the entrance of France by the Allies, the abdication of Napoleon, and the tragic hundred days, all of which, with later events, had their effects upon the school. Louis XVIII. proposed to change the organisations of the school and university, and a decree with this end in view was passed in February 1815. But when Napoleon returned from Elbe, a few days later, he entirely suppressed the new regulations, and re-established the Imperial University in accordance with the decree of 1808. And when the Empire finally fell, the ministers of Louis XVIII. abandoned the idea of changing the organisation, and themselves supported the Imperial system. The school existed up to 1822 under these rules, when it was decided that its place should be taken by Écoles normales partielles. Four years later the school was re-established, but in order not to excite memories of the Revolution and the Empire, it was named the "École préparatoire." Only in the name did this school differ from the old Normal School, and even that was restored by Louis Phillippe, Duke of Orleans, who, in August 1830, shortly after he became King of the French, issued an order that "the school devoted to the education of professors, and for some years carried on under the name of École préparatoire, is to reassume the title of École normale." A little later, the school was organised on the lines upon which the studies are carried there to-day. The duration of the course of study, which in the École préparatoire had been two years, was definitely fixed at three years,

and the sections of science and letters were more clearly separated than they had ever been before. After studying together during the first year, the science students, during the second and the third years, were arranged into two divisions, one of the physical and mathematical sciences, the other of natural sciences, the chemists being classified with the naturalists. In the second year the mathematicians and physicists had a few courses in common with the chemists and naturalists, but during the third year were kept altogether distinct.

The Government of Louis Philippe, which, in a way, established the fundamental system of primary instruction in France, gave the Normal School a firm standing by instituting competition and new classes; it also took steps to provide proper accommodation for the students. The buildings of the Plessis, where the studies were conducted, were falling to pieces, and it was recognised that new ones would have to be provided. In 1838 the site in the rue d'Ulm, now occupied by the school, was chosen; the plans were prepared, and money required to execute them was voted in the spring of 1841.

But six years passed before the work was done, and it was not until 1847 that the school was transferred to its new domicile, and the title of "École normal supérieure" was inscribed over the door. M. de Salvandy presided over the opening ceremony, and the director of studies, Dubois, who succeeded Cousin in 1840, read a summary of the history of the school. From that time until 1848, when Louis Napoleon became President of the French Republic, no change of importance occurred. The first event which, of the whole of the religious reactions favoured by the future Emperor of the French, foreshadowed rigorous changes in the school's regulations, was the substitution of M. Dubois by M. Michelle, rector of the Besançon Academy, in July 1850. The new director took the rank of inspector-general, and the school ceased to be represented upon the Council of the University. A year later, M. Vacherot, the director of studies, followed Dubois, and then M. Jules Simon, whose lectures were suspended at the end of 1851, resigned his connection with the school. The idea of suppressing the school altogether was afterwards seriously considered, but fortunately it was not carried into execution. Attempts were made to limit the freedom with which subjects were dealt, and, for a time, Protestants and Jews were refused admission. A better period commenced in 1857, when Nisard succeeded Michelle as the director of the school, and Pasteur became the director of scientific studies. Five science Fellowships were created in the following year, and the holders of them carried on researches under Henri Saint-Clair Deville and Pasteur, whose investigations increased the school's reputation.

After the affairs of 1870, which deposed Louis Napoleon and established the third Republic, Bersot was nominated director of the school by Jules Simon, and occupied that position until 1880. Under him, the constitution of the school was sustained, and brought back to what it was under the direction of Cousin and of Dubois. Bersot died in 1880, and the fifteen years that have elapsed since his death form the last period in the eventful history of the Normal School. M. Fustel de Coulanges was the director from 1880 to 1883, and since then the present director, M. Georges Perrot, has occupied that position. In 1880 a section of natural sciences was re-established, and this, with other improvements in the internal organisation, has assisted the school to the high place it now occupies.

The second part of the volume, from which many of the foregoing details were obtained, is taken up with biographies of the directors (each accompanied by a fine photogravure of the subject) and of papers referring to the men who have helped to develop the different departments of the school. Passing over the former section, we arrive at an account of the mathematical work at the school, by M. Jules Tannery. The high standing of this department may be judged by the fact that, of the six members of the Section of Geometry of the Paris Academy of Sciences, three belong to the Normal School. The Section of Astronomy contains two old students—one the present Director of the Paris Observatory. The school has contributed to this Academy the names of Pouillet, Delafosse, Pasteur, Jamin, V. Puiseux, P. Desains, Bouquet, Van Tieghem, Debray, Hébert, Tisserand, Fouqué, Wolf, Darboux, Troost, Mascart, Lippmann, Duclaux, Picard, Appel, and Perrier. M. Bertrand, the eminent Perpetual Secretary of the Academy, was one of the first among the illustrious men who have made the school what it is, and encouraged its students to scientific investigation. After him, Cauchy dominated mathematical education at the school. Hermite, Puiseux, Briot, and Bouquet were the close friends and disciples of this profound geometrician, who, during the early part of this century, gave mathematical science so great an impetus. Of these, only Hermite survives, and he celebrated his jubilee a few months ago. Among those who benefited by Hermite's instruction and counsel stand out the names of Baillaud, Charve, Floquet, and Pellet. Appel, Picard, and Goursat are among other students who have brought credit to their *alma mater*.

Verdet, whose electrical and optical researches are known to every physicist, became maître de conférences, that is, professor, of physics in 1848, and held that position until 1866. Mascart succeeded him for a few months, and was followed by Bertin-Mourot, who remained at the head of the physical department until 1884, since which year MM. Violle, Bouty, and Brillonin have filled the post.

Of all the teachers that the school has had, none have exercised greater influence upon it than Saint-Claire Deville. For thirty years he devoted his activities to the advancement of science at the school and to the welfare of his students. He succeeded Balard in 1851 as maitre de conférences in the section of chemistry, and at once commenced to reorganise the work and develop research. His advice to students who looked to books to supply them with subjects of investigation, was: "Fermez bien vite tous les liveres, venez au laboratoire, passez-y toute la journée, faites-y n'importe quoi, reprenez par exemple minutilusement un travail classique: vous êtes intelligent, vous ne tarderez pas à trouvez quelque résultat interressant." His numerous pupils profited by his invitation to work whenever possible in the laboratory, and many of them became his collaborators. Among these occur the names of Debray, Troost, Fouqué, Fernet, Lamy, Lechartier, Mascart, Isambert, Ditte, Joly, André, Angot, Dufet, Margottet, Chappuis, Parmentier, all of whom have advanced scientific instruction and research in France. Henri Deville never refused an investigator access to his laboratory, no matter what line of work was taken up, and the result was that not only chemists, but students of natural history, astronomy, and even an alchemist, availed themselves of the opportunity. After devoting the activities of a lifetime to science, Henri Deville died in July 1881, and by his death France lost one of its brightest lights.

Debray held a Fellowship at the Normal School when Henri Deville became the maître de conférences, and the two great investigators worked side by side for thirty years. He entered the school in 1847, and succeeded his master as professor at the Sorbonne and as maître de conférences at the school in 1875. He died in June 1888. Chemistry is at present under the charge of MM. Gernez and Joly.

The department of natural science in the school was established in 1880. The school had not existed until then, however, without paying any attention to the study of that division of scientific knowledge. M. Delafosse was maitre de conférences of zoology, botany, geo-

logy, and mineralogy so far back as 1827, and among the naturalists who taught one or other of the subjects before the new section was created were Hébert, Lory, Fouqué, Van Tieghém, Dastre, Perriér, Cornu, Giard, Le Monnier, and Bonnier. The feature of the instruction now given is the large attention paid to field work. Frequent geological, botanical and zoological excursions are made under the charge of the professors, both during the school year and the holidays. At the marine biological stations, holiday courses are always offered. Owing to the labours of Prof. de Lacaze-Duthiers, biological laboratories have been established at various points on the French coast. Since 1881, many students of the Normal School have worked at the stations at Roscoff, Banyuls, Concarneau, Wimereux, and Saint-Waast, and the knowledge they have thus gained from nature herself is far in advance of that received through lectures or from books.

Pasteur's connection with the school has a melancholy interest at the present time. Before he left the Faculty of Sciences at Lille, to become administrator and director of studies, he had made his important researches on the tartrates of soda and ammonia, and had commenced the study of fermentation. He therefore wanted a laboratory in which to continue his researches, but the school could not at the time offer him one. After a little difficulty, one small room, about ten feet square, was obtained, and in that restricted space he made some of his most valuable discoveries. This accommodation however, was gradually increased. In 1862 a large room was expressly constructed for Pasteur's work, and was added to from time to time as the value of the researches carried on came to be recognised. Finally, it was impossible for him to carry on his extensive researches under the hospitable roof in the rue d'Ulm, and he had to remove to a larger building. A few years later his work for science and humanity was recognised by the construction, at a cost of more than £100,000, raised by international subscription, of the Pasteur Institute in Paris, where the results of his researches are daily applied, and where the remains of the great investigator will finally rest.

The valuable *Annales d'École Normale* owe their commencement to M. Pasteur. The journal was first issued in 1864, and many important memoirs by members of the teaching staff, and by students, have appeared in it. Pasteur was editor from 1864 to 1870, and was succeeded by Henri Deville, who held the position until 1881, though the publication must have entailed pecuniary loss. Finally, the *Annales* were placed upon a firm footing by M. Zevort, Director of Secondary Education, who twelve years ago increased the subscription list by providing for the introduction of the journal into a number of *lycées*, and since then the assistance thus rendered has been continued by succeeding Directors of Higher and Secondary Education. M. Debray held the editorship of the *Annales* from 1882 to 1888, and M. Hermite now edits it, with an editorial committee comprising many of the most eminent men of science in France.

Many other names, in addition to those already mentioned, have contributed to the glory of the school. The work of Galois, for instance, whose short life ended in 1832, while still a student at the school, has had great influence upon the development of mathematics.

In the early part of this century, little attention was paid to astronomy at the Normal School. The mathematicians there produced a number of important memoirs on celestial mechanics, and made astronomical tables, but practical astronomy was entirely neglected. When Le Verrier became director of the Paris Observatory, he obtained permission for a limited number of students to work at the Observatory while still retaining their position in the school. Victor Puiseux and Paul Desains were the two first students selected, and they were succeeded by Paul Serret and Marié-Davy. Le Verrier thus opened a new career for students at the school, and the way they availed themselves of it is shown by the fact, that, in 1866, there were as many as fifteen of them upon the Observatory staff. Among the names of astronomers who were students at the school, are MM. Tisserand, Rayet, André, Angot, Stéphan, Simon, and Voigt; and at one time or another the school has provided directors for all the State observatories in France.

What more need be said? The names and works of the school's alumni are known and honoured throughout the scientific world, and that is sufficient testimony to the character of the instruction. The French Government is generous in its treatment of the school, but the expenditure is returned increased a hundredfold through the works of the students. And not only do these works benefit the Republic; they have an international value. Therefore the centenary which the school celebrated this year, interests all who are concerned with the advancement of natural knowledge.

R. A. Gregory.

THE "GEMMI" DISASTER.

A month ago, the Swiss newspapers were full of various accounts of a destructive avalanche which took place at the Gemmi on September 11, at 4 a.m. The first report read as follows: "A large part of the Altels glacier got loose and slipped down, covering three kilometres of ground on the Spital Alp, two hours' walk above Kandersteg. Men (6) and cattle (300) have been killed by the slipped mass. The break across the glacier may be seen from the valley with the naked eye. Help has been sent up from the villages of Leuk, Kandersteg, and Frutigen." (*Allg. Schw. Ztg.*, September 12.) More correct details afterwards decreased the loss of cattle by about one half, and the whole damage is estimated at from 60,000 to 80,000 francs.

The part concerned will be perfectly familiar to many English travellers. Few foot-tourists in Switzerland miss the Pass of the Gemmi, which bridges the beautiful limestone mountains between Canton Bern and Canton Wallis at their western end. The tourist coming from the North leaves the broad Aare Valley of Canton Bern and its lakes at Thun, and ascends gradually through the lateral Kander Valley towards the glaciated chain of the Diablerets, Oldenhorn, Wildstrübel and Altels on the southern horizon. The characteristic group of snowy summits known as the Blümlis Alp closes in the southeastern. The valley itself is bestrewn with gigantic remnants of old mountain-slips, now clad with fir-tree and a rich flora. At Kandersteg it narrows, long moraines fringe the mountains, and the driving-road is left for a a steep winding footpath which climbs the mountain-sides beneath the shade of densely-grown larch and fir. The main stream hurls over rocky escarp and raves in deep ravine. A sudden opening in the wood discloses the tributary stream of the Gastern, its grey cliffs, and tumbling waterfalls; surely one of the most picturesque glens in the Alps!

Immediately beyond this point of view, the path descends slightly for a short distance and bends round the base of a wooded hill, known as the *Stierenbergli*, before it once more rises to the mountain pasturage and châlets of the *Spital*. Here, the sound of cow-bells rings over a grassy river-flat, hemmed in east and west by mountain ridges, northward by a thick tongue of moraine. Only one steep, narrow passage defiles the northern rocks and marks the contact of the Altels range with the moraine tongue. A dammed-up lake basin, often dry in summer, lies on the other side of the moraine where the road leads to the cosily-sheltered Schwarenbach Inn. Three-quarters of an hour's farther walk on rocky shelving

ground takes the tourist past the Daubensee to the height of the Gemmi Pass and the Hotel.

Such was the walk to the Gemmi before the avalanche occurred. Now the broad pasturage flat, the narrow defile above it to the Schwarenbach Inn, as well as several passages of the road below, especially the "Stierenbergli," lie beneath masses of ruin and disorder. Fir-slopes have been felled at one blow. Dismembered parts of cattle have been floated hither, thither, in the ice-stream. What makes it the sadder is that all had been in readiness on the [illegible] Alp for the departure of the herd-boys and [illegible] the following day to their villages in Wallis.

[illegible] Altels M[illegible] D[illegible] and fragments of chalet in the ice-stream.

[illegible] the cause of the disaster was the fall of the ice-mass, it must not be forgotten that the actual destruction [illegible] wind pressure ("Windschlag") in [illegible] of the falling mass. Living things and timber are [illegible] to the ground, or borne to considerable distances. The mass of ice then buries all beneath tons of weight, and transports still farther, tearing and breaking [illegible].

The enormous rush of wind, together with the terrifying sounds of the avalanche, gave the people of the neighbourhood a rough awakening from their night's rest. They thought an earthquake was convulsing them. Only one witnessed the coming of the avalanche, that was the waitress at the Schwarenbach Inn, who had just risen to prepare an early cup of coffee for some of the guests. She rushed out, in time to see the ice skimming the road's corner on its way to destroy the Spital Alp. Had the fall taken place half a day sooner or later, tourists must inevitably have suffered on the much-frequented path.

Dr. Albert Heim, Professor of Geology at Zurich, was at once telegraphed for to make a thorough investigation of the disaster. The result of his examination will not be fully published until the end of the year. Meantime some of the more exact details may be stated here. The accompanying photographs are a few of those taken at Prof. Heim's wish immediately after the disaster.

The first shows the break in the ice on the Altels Mountain. It occurred near the foot of the nevé or "Firn-snow" region of the Altels glacier, at a height of 3300 metres (11,000 feet). The mass of ice which broke away measured about 300 metres in length, 200 metres in breath, and 30 metres in thickness. It streamed down the steep-dipping, smooth slabs of limestone rock on Altels, and spread itself out fan-like on the Spital Alp, 1900 metres high (6270 feet). The vertical height of the fall was therefore some 4700 feet. The immense impetus thus gained caused the ice to pursue its course up the steep incline of the "Oeschinen Grat." The main part in the centre of the avalanche "fan" dashed itself with its spray of ice-dust and débris against the ridge, surmounted it in parts as high as 2360 metres, over 7700 feet, and pitched many fragments upon different levels on the other, or Oeschinen Valley, side of the ridge. The outer wings of the fan, on the other hand, curved backwards; that on the north side can be traced as a return stream from Winteregg to the Stierenbergli corner of the Gemmi road referred to above (Fig. 2).

This return stream did especial damage to the trees; and nothing can be more striking than the sight of the long larch and fir trunks felled in one and the same direction, and clean-cut along a definite line. One hillock has been stripped of its timber on one side, while no harm has been done on the other. The course of the avalanche has left its trail of stems; up torn roots, ravaged châlet, dead cattle, even cheeses may be distinguished jammed in the general heaps of ruin.

The result on the ice of its own motion and pressure during its fall deserves attention (Fig. 3). The photograph shows the typical form which the ice takes, viz. that of har

rounded pieces of ice of all sizes mixed in loose ice powder. Friction produces various markings on the rolled ice.

There is altogether a remarkably small proportion of carried *rock*-débris mixed with the ice. The whole field of ice on the Spital Alp simply portrays a "Staub Lawine," or dust avalanche on a large scale. In the course of a few years nature itself will have removed the last signs of a wreckage which at present hundreds of willing hands are doing their best to clear away in part from road and Alp.

MARIA M. OGILVIE.

FIG. 2. Return stream covering the Gemmi road at the Stierenberg corner.

FIG. 3. Ice structure in the avalanche.

THE LATE PROFESSOR HOPPE-SEYLER.[1]

ERNEST FELIX IMMANUEL HOPPE[2] was born in Freiburg on the Unstrut (Saxony) on December 26, 1825. At the age of nine he lost his mother, and at eleven, being left an orphan by the death of his father, he was taken charge of and educated by the governing body of an endowed institution in Halle. After the completion of his school course he commenced in 1846 the study of the natural sciences as a student of the University of Halle. Migrating early in his student's career to Leipzig, he had the good fortune to lay the foundations of his knowledge of anatomy and physiology under the three distinguished brothers Weber (Ernst Heinrich, Wilhelm and Eduard), to study chemistry under Erdmann, and under the eminent physiological chemist Karl Gotthold Lehmann, medicine under Oppolzer, surgery under Günther, and pathological anatomy under Bock. Hoppe spent the last two semesters of his student's course in Berlin, following the courses of Romberg, Langenbeck and Casper. He took the degree of Doctor of Medicine in 1850, presenting a dissertation "De cartilaginum structura et chondrino nonnulla," which he dedicated to his former master E. H. Weber, and which indicated the impulse he had received towards anatomical as well as chemical investigation, on the one hand through the influence of the Webers, on the other through that of K. G. Lehmann.

Having settled in medical practice in Berlin, Hoppe was appointed medical officer to the workhouse, and whilst occupying this post, devoted himself to researches, partly chemico-physiological and partly clinical. To the former class belong investigations on cartilage bone and tooth, as well as chemical analyses of certain so-called transudations; to the latter, studies of which the object was to discover the physical principles which underlie many of the phenomena revealed by the percussion and auscultation of the chest in disease. In 1856, Hoppe was appointed Prosector in the University of Greisswald, where he qualified as Privat-docent: here, however, he only remained until 1858, when he was recalled to Berlin by Virchow, in order to act as his assistant. Virchow had just been appointed the first ordinary professor of pathological anatomy in the University, and Hoppe, as his only assistant, was at first called upon to take a part in all the work of the Pathological Institute, whether anatomical or chemical. Very soon, however, he was enabled to confine his attention to researches in physiological and pathological chemistry, and to the superintendence of the chemical laboratory of the Insti-

[1] Though some weeks have elapsed since the death of this eminent man of science, a brief account of his life and an attempt to convey some idea of the part which he played in the advancement of physiological chemistry may not prove uninteresting to the readers of NATURE. In the preparation of this paper I have been greatly assisted by the information contained in an article which appeared in the *Vossiche Zeitung* of August 12.—A. G.

[2] The subject of this notice changed his name from Hoppe to Hoppe-Seyler somewhere about the year 1862.

tute. In 1860, Hoppe was appointed an extraordinary professor in the philosophical faculty of the University of Berlin. In 1861 (he had now assumed the name of Hoppe-Seyler) he was appointed to the chair of Applied Chemistry in the University of Tübingen, where he had as colleagues the botanist von Mohl, the physiologist Vierordt, the anatomist Leydig, the chemist Strecker, and the great physician Niemeyer.

It was whilst in Tubingen that Hoppe-Seyler published (1866–1870), under the title of "Medicinisch-Chemische Untersuchungen," a series of valuable papers by his pupils and himself, some of which will be always referred to by thorough students of physiological chemistry; such are the researches of Diakonow on lecithin, of Miescher on nuclein, and Hoppe-Seyler's own papers on hæmoglobin, its compounds and certain of its derivatives.

When, in 1872, after the conclusion of the Franco-German war, the German Government gave to Strasburg the new and splendidly-endowed Kaiser Wilhelm's Universitat, Hoppe-Seyler was one of the distinguished men chosen to fill its chairs, being appointed to the only ordinary professorship of Physiological Chemistry in the German empire. Among those who were called with him, and who were destined to shed a brilliant lustre on the new academy, which had arisen Phœnix-like out of the ashes of the old Strasburg, were such men as Waldeyer, Recklinghausen, Leyden, Gusserow, Schmiedeberg and Fluckiger. No wonder that Strasburg has already become one of the chief centres of research in Europe!

Amongst the laboratories—the so-called institutes—which are clustered around the Hospital of Strasburg, is the so-called Physiologisch-Chemische Institut, in which since his appointment Hoppe-Seyler has continued the work which he had begun in Berlin and in Tübingen, surrounded by pupils, many of whom—I shall merely name Baumann, Brieger, Kossel, and Thierfelder—have won for themselves honourable positions in contemporary science, and for their master the reputation of a great teacher, in the best sense of the term. Here Hoppe-Seyler worked until the very eve of his death. Leaving Strasburg apparently in the fulness of health and vigour to enjoy a few weeks of rest on his property by the shores of the Lake of Constance, Hoppe-Seyler was to be spared the misery of prolonged illness. Some sudden and unsuspected cardiac mischief brought to a standstill the life of a man of singularly great activity, intellectual as well as physical. He died on the forenoon of August 10, 1895.

Arthur Gamgee.

THE FUNERAL OF PASTEUR.

AMID signs of national sorrow, the funeral of Pasteur took place on Saturday last. France, more than any other nation, knows how to do honour to the memory of those who have contributed to her greatness, and by giving a national funeral, as well as taking the cost of it upon herself, she has once more shown the esteem in which she holds those who have devoted their lives to the increase of the world's knowledge and happiness. How very full was this expression may be gathered from the report of the *Times* correspondent at Paris. We read: "Quite a small army of infantry, marines, cavalry, artillery, and municipal guards, mounted and on foot; deputations from all the schools and learned societies; most of those who speak and of those who govern and command in the name of France, came to render homage to the stainless glory of this Frenchman, whose genius devoted its efforts to the whole of mankind, and who deserves the gratitude of the world, not merely for the labour which he accomplished but for the new paths which he opened to science by the fresh discoveries which he made for the benefit of mankind." Shortly after ten o'clock on Saturday morning, the troops and innumerable deputations, which had assembled in and near the Pasteur Institute, marched past before the coffin containing the body of the illustrious investigator. The funeral procession was then organised. General Saussier, surrounded by his staff, and followed by the first division of infantry, preceded the hearse, and behind him came a long line of deputations, many of which had wreaths in their centre. A number of wreaths were borne on litters, and others were carried on six cars, each drawn by a pair of horses.

"Along the route from the Rue Dutot to Notre Dame," says the *Times* correspondent, "the compact and silent crowd respectfully uncovered their heads as the hearse passed, and the two thousand soldiers and policemen, drawn up in line to keep the way clear, had absolutely nothing to do. The pall-bearers were M. Poincaré, M. Joseph Bertrand, M. Georges Perrot, Dr. Brouardel, M. Gaston Boissier, and M. Bergeron. After marching for an hour and a half along the left bank of the Seine, the procession reached the square of Notre Dame. The aspect of the Cathedral was most impressive. The presence of President Faure, the Grand Duke Constantine, Prince Nicholas of Greece, Cardinal Richard, the whole of the Diplomatic Corps, the Ministers, the Institute of France, the office-bearers of the Senate and the Chamber of Deputies, the red-robed Judges, the members of the University faculties, in orange, red, and crimson robes, and the other distinguished persons invited—all this display of official mourning was coupled with and yet eclipsed by the profound silence, the manifest grief. The immense crowd was a rare and impressive, if not a unique spectacle."

The Royal Society was represented by Mr. W. T. Thiselton-Dyer, C.M.G., Director of the Royal Gardens, Kew. At the final funeral, which will be held in connection with the Centenary of the Institute, on the 25th inst., several of the Officers and Fellows of the Society will be present, together with many delegates from other of our learned societies.

After the service in Notre Dame, the coffin containing Pasteur's remains was removed to a catafalque outside the Cathedral, and M. Poincaré delivered an oration before it, on behalf of the Government.

Thus does France venerate the memory of her noblest son. But France is not alone in her grief. The human race joins with her in mourning the loss of one who has done so much for humanity and science. The name of him to whom the world owes so much good is imperishable.

NOTES.

IN July of this year, a special Parliamentary Committee, of which Mr. Rhodes, the Premier, was a member, sat in Cape Town to consider the advisability of beginning a systematic geological survey of the Colony. The Committee, after hearing evidence, recommended the House of Assembly to appoint a standing Commission which should take charge of the work, and become in the first instance responsible for its being efficiently carried out. Parliament having accepted this recommendation, the warrant appointing the Commission has been duly drawn up and signed by the Governor of the Colony. The following gentlemen compose the Commission: the Hon. J. X. Merriman, M.L.A.; Dr. Gill, Astronomer Royal; Dr. Muir, Superintendent General of Education; Mr. Charles Currey, Under-Secretary for Agriculture; and Mr. Thomas Stewart. The three first-mentioned are Trustees of the South African Museum, Cape Town, and it is intended that the geological staff shall have its headquarters in the new museum building, which is just approaching completion. In past years a great

amount of detached work, chiefly of the nature of prospecting and reporting upon mineral occurrences, has been done in Cape Colony, while many European geologists have written papers dealing with the rocks, fossils, and in some cases the structural characters of different portions of the Colony which at various times they happened to have visited. The Commission intends, as one of its first duties, to have a bibliography of all such papers and reports published, but will at the same time have an organised systematic scheme of field work entered upon. A topographical map on a scale of two miles to an inch has already been published for about one-twelfth of the entire area of the Colony, and it is intended to utilise this for the geological details.

DR. W. S. CHURCH will deliver the Harveian oration before the Royal College of Physicians, on Friday, October 18.

PROF. RAOULT, of Grenoble University, has been awarded the prize of twenty thousand francs given biennially by one of the bodies constituting the Institute of France, and awarded this year by the Academy of Sciences.

WE regret to notice the death of Prof. A. von Bardeleben, the eminent surgeon, and for many years one of the Presidents of the Berlin Medical Society. The death is also announced of Baron Felix Larrey, member of the Paris Academy of Medicine, and author of a number of works on military surgery.

THE *Bulletin* of the Royal Gardens, Kew, announces that Sir Joseph Hooker has presented the Gardens with a replica of a portrait of the late Dr. T. Thomson, F.R.S. Dr. Thomson was the first botanist to enter the Karakoram mountains, and was for some time Director of the Calcutta Botanic Gardens.

DURING the Leyden Zoology Congress a small volume, entitled "Guide Zoologique de la Hollande," was presented to the members. This little book, containing a number of photographs, was compiled by the General Secretary to the Congress, Dr. Hoek, and is full of information on the zoological laboratories, the museums, the zoological station and the zoological gardens, as well as concerning the study and the teaching of zoology in Holland. Several chapters are, moreover, devoted to the fauna of the country.

AT last week's meeting of the Pharmaceutical Society of Great Britain, the Hanbury Medal was presented to Dr. A. E. Vogl, Professor of Pharmacology in the University of Vienna, through Count Clary, Prof. Vogl being unable to attend in person. The medal is awarded biennially in accordance with the condition of the Hanbury Memorial Fund, and the award rests with the Presidents of the Pharmaceutical Society, Linnean Society, Chemical Society, and the British Pharmaceutical Conference. The first presentation was made in 1881, the recipient being Prof. Flückiger.

AT the Royal Microscopical Society, on Wednesday, October 16, the following papers will be read:—"On the Division of the Chromosomes in the Pollen Mother-Cell of Lilium," by Prof. J. B. Farmer; "New and Critical Fungi," by G. Massee; "A Fluorescent Bacillus," by F. J. Reid.

THE inaugural lecture of the newly-instituted "Course of Scientific Instruction in Hygiene and Public Health" at Bedford College for Women, was delivered by Dr. Louis Parkes on Saturday afternoon, October 5. The course aims at promoting systematic instruction in hygiene and all those allied branches of science necessary to a thorough knowledge of sanitation and laws of health, and so qualifying women to become teachers and lecturers, and inspectors of workshops and factories where female labour is employed.

A MEETING of the Institution of Mechanical Engineers will be held on Wednesday, October 23, and Thursday, October 24, a the Royal United Service Institution, Whitehall. The chair will be taken by the President, Prof. Alexander B. W. Kennedy, F.R.S., and the following papers will be read and discussed, as far as time permits:—"The Electric Lighting of Edinburgh," by Mr. Henry R. J. Burstall; "Report on the Lille Experiments upon the Efficiency of Ropes and Belts for the Transmission of Power," translated by Prof. David S. Capper; "Observations on the Lille Experiments upon the Efficiency of Ropes and Belts for the Transmission of Power," also by Prof. Capper.

THE death of Moritz Willkomm, the eminent botanist and geographical explorer, is announced in the *Geographical Journal*. Of his life we read:—"Born in 1821, at Herwigsdorf, in the kingdom of Saxony, after 1841 he studied medicine and natural science at Leipzig. In 1844 he for the first time visited the Pyrenean peninsula, which he subsequently traversed so often, sometimes by the year together, making thorough investigations into the botanical, geognostical, and geographical relations of the country. After having, in 1852, gained some experience as teacher of botany at Leipzig, and having been called thence first to Tharandt, and afterwards, in 1868, to Dorpat, he occupied the chair of Botany at the German University at Prague from 1873 until the receipt of his pension in 1892, being at the same time Director of the Botanical Garden in that city. He did much good work by his rich botanical collections, principally from Spain and the Balearic Isles, as well as by his special botanical works dealing especially with the descriptive side of the science; whilst as a geographer he did lasting service, not only in connection with the geography of plants—in particular in South-West and Central Europe—but also by his comprehensive geographical description of Spain and Portugal; and, above all, he threw light on the geography of Austria by his excellent work on the Böhmerwald (1878), which region he was the first to throw open to science in its most inaccessible parts, still at the time clothed with primeval forest."

WITH reference to the letter by Mr. Pillsbury on "Colour Standards" (NATURE, August 22, p. 390), Mr. J. W. Lovibond writes from Salisbury:—"In justice to myself, may I be allowed to point out that the difficulties named no longer exist, since it remains as an experimental fact that the solution of every position which Mr. Pillsbury describes as desirable and lacking is now a matter of everyday routine in many laboratories and manufactories. . . . Every sensation, whether of light or colour, which can be differentiated by the vision can be matched by means of the Tintometer Standard Glasses, and defined by means of a system of colour terms; the colour sensation itself can be reproduced at any future time by simply using the matching glasses. The operation of matching a colour is so easy that in those factories where frequent changes of colour require noting, or where it is necessary to work up to a given colour, an intelligent workman is found competent to effect them."

THE current number of *Himmel und Erde* contains the concluding part of two interesting articles on scientific balloon ascents, by Dr. R. Süring, of Potsdam. The author briefly reviews all ascents since that by Jeffries and Blanchard on November 30, 1784, and shows that relatively little use has been made of the observations, probably because they have not always been free from objection, or from the fact that most ascents have been of an isolated character. The principal exceptions, among the older ascents, are the celebrated voyages of Welsh a Glaisher, and more recently those made by the Bavarians and

Russians: the latter dealing more especially with wind conditions in high and low barometric pressures. The German Society for the promotion of scientific balloon ascents, under the patronage of the Emperor, will probably obtain important results, and solve several open questions relating to cloud formation, and atmospheric electricity under various hygrometric conditions of the atmosphere.

A SUSPENSION for physical instruments free from the vibrations of the laboratory would be an inestimable boon to physicists, especially in crowded cities. At Leyden University, Prof. Einthoven mounted his delicate capillary electrometer on an iron plate floating on mercury. This device was exceedingly successful, although somewhat cumbersome and bulky, and he was thus enabled to take a photographic record of the instrument magnified 800 times. Sir G. B. Airy was in the habit of placing his artificial horizon upon a table suspended by caoutchouc bands attached to another table similarly suspended, the arrangement being repeated three times. This, however, was even more cumbersome. Now Herr W. H. Julius, in *Wiedemann's Annalen*, describes a contrivance which is both simple and effective. It consists of a small circular table suspended by three vertical wires about 6 or 8 feet long, the ends of which form the points of an equilateral triangle. A movable weight is attached to a rod projecting downwards from the centre of the table. It can be clamped in any position, so as to bring the centre of gravity of the table and the instrument into the plane of the table itself. Any lateral displacement of the upper ends of the wire will start waves down the wires, which will arrive at the table simultaneously, but will only affect it perceptibly when the period of the disturbance coincides with the period of oscillation of the table about the point of suspension. Even then the axis of the table is always strictly vertical. To clamp the oscillations peculiar to the suspension the author attached little vanes, dipping into oil or water, to the table. With a rough preliminary apparatus constructed in this manner, the author succeeded in reducing the vibrations to one-tenth of their original amplitude.

THAT sedimentation plays an important part in the purification of water, was shown as long ago as the year 1886 by Dr. Percy Frankland in the case of his laboratory experiments on the removal of micro-organisms from water. That it is a factor of great importance in the storage of water in reservoirs, was also shown by him in his investigations at the London water-works: but quite recently Dr. H. J. van 't Hoff has indicated how this now recognised process of sedimentation may be taken advantage of in the abstraction of tidal water for purposes of water-supply. It appears that the city of Rotterdam derives its water-supply from the river Maas, and that the Company's intake is situated within the tidal area of the river; the water is, however, only abstracted at particular times, *i.e.* two hours after high-water has been reached. During this period the river is at rest, and sedimentation can proceed unhindered, and Dr. van 't Hoff estimates that at least 50 per cent. of the bacteria present are [illegible] during this time of comparative stagnation. Unlike the city of Hamburg, which before and during the great cholera epidemic [illegible] tidal water from the river Elbe, and distributed it in a raw condition in Rotterdam, the Maas water is submitted to filtration before delivery. In consequence, however, of a very large demand on the resources of the water-works, [illegible] considerably higher than it should be; and this, combined with the unpleasant circumstance that [illegible] by conducting it into the river, [illegible] a bad bacterial filtrate. Dr. van 't Hoff [illegible], unfortunately, give any figures for the [illegible] very [illegible] bacteriological [illegible] Rotterdam water-works are doubtless [illegible] the improvement which takes place in this tidal water through sedimentation, rendering the raw water comparatively easy to deal with, whilst its microbial contents after the stagnation period average only from 4,000 to 10,000 per cubic centimetre, a remarkably small number for a polluted water.

MESSRS. OLIPHANT, ANDERSON, AND FERRIER are about to issue a new popular science series for children, under the title of "Science Talks to Young Thinkers." The first volume is "Nature's Story," by Mr. H. Farquhar.

THE last part of "The Natural History of Plants," by Kerner and Oliver, which Messrs. Blackie have for some months been issuing, has just appeared, and the whole of that excellent work can therefore now be obtained in volumes.

MESSRS. CASSELL AND CO. have issued the first part of a "new and revised edition" of Sir Robert Ball's "Story of the Heavens." We hope that succeeding parts have been brought up to the present state of knowledge, so that the edition will really be a revised one.

SEVERAL years ago it was intimated by a circular that Dr. Buchanan White was engaged in the preparation of a Flora of Perthshire, which he hoped to issue after a brief period of time. Dr. White's death, last December, prevented its issue by himself, but he left it in a state that permits of its immediate publication: and we are glad to notice the announcement that the book is to be issued on behalf of the Perthshire Society of Natural Science. Prof. Trail, F.R.S., has undertaken to edit it, and to preface it with a sketch of the author's life and scientific work.

A SERIES of five simply-worded books on wild flowers, by Dr. M. C. Cooke, has been published by Messrs. T. Nelson and Sons. The volumes are entitled "Down the Lane and Back," "Through the Copse," "A Stroll in a Marsh," "Around a Cornfield," and "Across a Common." Written in an attractive conversational style, and with scanty use of the "hard words" which children, and even those of older growth, always associate with the study of nature, the books are well suited to the juvenile public for whom they are intended.

WE are glad to note that the Harveian oration delivered by Dr. Lauder Brunton before the Royal College of Physicians last October, and printed in full in these columns at the time, has been published in the form of a handy volume by Messrs. Macmillan and Co. It will be remembered that the subject of the oration was "Modern Developments of Harvey's Work"; and those who know how well and fully Dr. Brunton treated his subject, will be gratified at the publication of the oration in a convenient form. The volume is dedicated to Sir J. Russell Reynolds, the President of the Royal College of Physicians.

WE have received the second part of Mr. J. W. Taylor's "Monograph of the Land and Freshwater Mollusca of the British Isles," from Messrs. Taylor Brothers, Leeds, and are pleased to see that the high standard of excellence to which we called attention in our notice of the first part is well sustained. The descriptive text is clear, and generally accurate, while the paper, print, and illustrations (coloured and otherwise) are all praiseworthy. The present part practically completes the consideration of the shell, and the next issue will be devoted to the animal and its organisation.

THE "Zoologisches Adressbuch," which R. Friedlander and Sohn, Berlin, have edited and published in connection with the Deutsche Zoologische Gesellschaft, will prove of very great assistance to workers in all parts of the world. The volume contains the names and address of zoologists, anatomists, physiologists, and zoo-palæontologists of all countries. The classification is according to countries, the towns of which are

arranged (with a few exceptions) in alphabetical order, while the names follow the same order. Each name is followed by a full address, and by an indication of the special branch or branches of study in which the person it designates is interested. To give an example of the scope of the contents, it may be said that under London we find the names of the professors and assistants in the zoological and kindred departments in the various colleges and medical schools: the staffs of the departments of zoology and geology in the Natural History Museum; some of the members of the Geological Survey of England and Wales; a list of the members of the Zoological Society; the names and places of meeting of a number of London and suburban scientific societies interested more or less in zoology; and lists of draughtsmen, opticians, publishers, and of taxidermists and dealers in animals. In some cases the lists are much fuller than in others, owing probably to the fact that some colleges and institutions furnished the publishers with more detailed lists than others. But though a few names are omitted from the places where one first looks for them, they can in most cases be found somewhere in the volume. Very valuable is an index of the names arranged in groups according to the subjects especially studied, and a geographical index. And, finally, the personal index at the end of the volume renders it possible to find the name, address, and special work of any zoologist entered in the work in a few moments. It is well known that the Germans excel in producing directories of the kind before us, and, so far as we can make out, the present work will sustain their reputation. Being international, the directory will help to bring together observers accumulated in widely separated regions of our globe, and so will lead to a better knowledge of the world's fauna. We congratulate Messrs. Friedländer upon the enterprise they have shown in preparing and producing such a useful work; and we hope the time is not far distant when the designations of students and investigators in the domain of physical science will be brought together in a similar directory.

THE additions to the Zoological Society's Gardens during the past week include a Black Ape (*Cynopithecus niger*) from Celebes, presented by Mr. Frank Greswolde Williams; a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Mr. H. Small; a Bonnet Monkey (*Macacus sinicus*, ♀), a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mrs. Lionel Smith; a White-tailed Ichneumon (*Herpestes albicauda*), two Blotched Genets (*Genetta tigrina*) from Natal, presented by Mr. W. Champion; a Cape Hyrax (*Hyrax capensis*), two Suricates (*Suricata tetradactyla*) from South Africa, presented by Mr. J. E. Matcham; two Norwegian Lemmings (*Myodes lemmus*) from Norway, presented by Mrs. Haig Thomas; a Passerine Parrakeet (*Psittacula passerina*) from Brazil, a Silky Cow-Bird (*Molothrus bonariensis*), a Red-crested Cardinal (*Paroaria cucullata*) from South America, presented by Mr. R. Norton; two Common Kingfishers (*Alcedo ispida*), British, presented by Mr. J. A. Clark; a Passerine Parrakeet (*Psittacula passerina*) from Brazil, a Tuberculated Iguana (*Iguana tuberculata*) from the West Indies, two Common Teguexins (*Tupinambis teguexin*) from South America, deposited.

OUR ASTRONOMICAL COLUMN.

MEASUREMENT OF PLANETARY DIAMETERS.—In a paper giving particulars of measurements of the polar diameter of Mars (*Astronomical Journal*, No. 354), Prof. Campbell gives an interesting summary of the conditions of planetary measures in general. He points out that measurements of diameter are affected by a variety of errors, among them being spherical and chromatic aberration, imperfect atmospheric conditions, irradiation, diffraction, and imperfect focus, all of which tend to increase the apparent diameter of the object; while, in addition, personal equation and accidental errors may also affect the results. The effects of spherical and chromatic aberration, as well as of diffraction, may be regarded as constant throughout a series of measures of any given object. Differential refraction can be satisfactorily corrected for, but the irregular refraction caused by the unsteadiness of the atmosphere, and resulting in "poor seeing," may produce very large errors indeed. The apparent increase of diameter due to irradiation may be regarded as sensibly constant with any given telescope, eyepiece, planet, and background. Imperfect focus may produce considerable and variable errors: in the 36-inch Lick telescope, an error of a thousandth of an inch in focussing increases the diameter of a planet by 0″·02. Experiments as to the best method of procedure were made by Prof. Campbell in June and July, 1894, with the result that the following programme was adopted in the case of Mars: (*a*) All the observations were made with the sun above the horizon, and the advantages of a bright sky background were very marked; it was believed to reduce all the errors, except possibly that of personal equation. (*b*) Observations were only made in a tranquil atmosphere. (*c*) The same eyepiece was used throughout. (*d*) An eyepiece cap with a very small aperture was employed. (*e*) The observer's eyes were always similarly situated with respect to the threads of the micrometer. (*f*) The micrometer threads were always placed parallel to the great circle passing through Mars and the sun. (*g*) The micrometer threads were placed directly upon the opposite limbs of the planet.

Following this programme, and adopting Young's value of 1/219 for the polar compression, the most probable polar diameter of Mars, at distance unity, was found to be 9″·25 ± 0″·012, while the equatorial diameter resulting from the measures was 9″·30.

THE CRATERS ON THE MOON.—Much has been learnt about the configurations of the lunar surface since the idea of examining very greatly enlarged photographs came into practice. It was only natural, however, that many interested in the subject should have looked upon the interesting results of Dr. Weinek with scepticism, for it was hard to believe that such detail structure could be so perfectly secured on the photographic plates. Such doubts as to their existence were somewhat increased by the fact that many details were invisible to eye observations, or at any rate were thought to be, but the fact was not sufficiently grasped that the photographic plates showed only the detail as it appeared at the moment of the exposure, which might have differed considerably from that which preceded it or, followed it by a few seconds.

Every confidence is now placed in the photographic records, and under suitable and similar observing conditions the eye should be ably to verify them directly. M. C. M. Gaudibert, in *Astr. Nach.* No. 3310, tells us of his discovery, with an instrument of 200 m.m. aperture, by eye observations alone, of a small crater only 800 metres in diameter. It lies on the top of the central mountain of Albategnius. This crater has been subsequently found by Dr. Weinek on a negative taken by MM. Loewy and Puiseux 1894, February 13, 4h. 0m. Mean Time Paris.

A diligent search by M. Gaudibert has also enabled him to secure the necessary observational conditions to see the two small craters discovered by Weinek near the crater and to the east of the Rephees mountains.

SUGGESTION FOR ASTRONOMICAL RESEARCH.—Dr. Isaac Roberts draws attention to a piece of useful astronomical work which may be performed by those who take a practical interest in the subject, namely, to determine what changes, if any, have taken place among the stars in the regions photographed by him at intervals during the past eight years. In the first instance it will only be necessary to compare the earlier photographs published in his well-known "Photographs of Stars, Star Clusters, and Nebulæ" with the new series now appearing in *Knowledge*; but arrangements are being made which will enable investigators to refer to glass positives, or the negatives themselves, to settle any doubtful points. The photographs being enlarged to the same scale, comparative measurements may readily be made by means of a *réseau* ruled on glass, and a transparent protractor will enable position angles to be determined. The scale of the photographs is such that any change of position exceeding three seconds of arc may be detected by careful measurements. "Thus, a system of astronomical research would be inaugurated, that must eventually add largely to existing knowledge."

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

ON Thursday, September 12, the President's address was delivered. The address was followed by craniological papers.

Sir W. H. Flower exhibited four skulls of the aboriginal inhabitants of Jamaica, who had disappeared before the English occupation in the seventeenth century. They resemble the Carib type, and have been more or less markedly deformed during life.

The President, in the absence of Dr. J. G. Garson, gave an account of the physical characteristics of the "New Race" lately discovered in Egypt. Some 200 skulls were secured, and parts of 400-500 skeletons. The average index of length lies between 73 and 75: the alveolar index shows three predominant types, about 94, 96, and 99·5, which are confirmed by the male and female indices taken separately, and indicate a mixture of races. The nasal index is 54: wider than the European (47), and Egyptian and Guanche types (49), which are thus excluded. The great excess, especially from one of the sites explored, of female skulls of very small capacity is explained by supposing a segregation of a part of the race, and subsequent marriage of the smaller-headed women into the normal branch. The well-known decrease of cranial capacity in tropical, as compared with arctic and temperate races, suggests that the new race originated in tropical Africa. But the type of skull appears to be distinct from that of the negro: and the hair which has been found is either straight or wavy.

Each afternoon of the meeting was devoted to a lantern lecture of a somewhat more popular kind than the morning's work. On Thursday the President described the remains and civilisation of the "New Race" in Egypt, whose physical features had been already examined.

Several rites were discovered this winter between Ballas and Nagada, near Thebes, of an entirely un-Egyptian character. All the pottery was hand-made, though the potter's wheel had long been known in Egypt: and though metal was not entirely unknown, the great majority of the implements were of very delicately worked flint. The long knife-blades, and the forked spear-heads with peculiar hafting, for bringing down running deer, are particularly notable. Very beautifully formed jars of hard stone, with perforated ears for suspension, are also a characteristic manufacture, and are imitated in clay with painted marbling, and also later by the native Egyptians. Extensive cemeteries have been explored, and the manner of interment has been determined: the bodies were buried on one side in a contracted posture, with many vessels and other funeral furniture, and with "a great burning" as part of the ceremony. This, and the peculiar physical type of the people seem to connect them with the ancient Amorites of Southern Palestine; while, on the other hand, they seem to have invaded Egypt from the Libyan Desert, and to belong closely to the early inhabitants of the north coast of Africa. The date of their occupation of Egypt is fixed by the interposition of their tombs between those of sixth and twelfth dynasty Egyptians: so that their presence explains the fall of the Pyramid-Building dynasty, and the gap which has been observed at this point in the sequence of Egyptian history.

On Friday, Mr. H. W. Seton-Karr exhibited a large series of flint implements from Somali-land, and of illustrative photographs. The flint is of local origin, and a number of factories has been identified.

Mr. W. J. Knowles sent a "striated flint implement" from the North of Ireland, which gave rise to some discussion as to its origin.

Mr. B. Harrison contributed a report on the plateau flints of North Kent.

Mr. H. Stopes exhibited graving tools from the terrace-gravels of the Thames Valley and Palæolithic projectiles. In discussion, however, the human workmanship of some of the specimens was called in question.

The President gave a demonstration, with numerous illustrations, of flint and metal working in ancient Egypt. The earliest implements in Egypt are of Palæolithic types, found undisturbed and deeply stained by exposure, on the surface of the desert, 800-1200 feet above the Nile Valley. More advanced workmanship, with long parallel flaking, appears in the gravels of the Nile, 30 feet above the river. No intermediate stages are known between these and the rectangular-faced flakes of the fourth dynasty. The "New Race" which overthrew the Pyramid-builders surpassed all known flint-workers in the length, flatness, and regularity of their knives, javelin-heads, and sickle-flints. Bangles and other ornaments of great delicacy were made of the same flint. Under the XII. dynasty straight-backed and curved knives, adzes, axes with lugs, scrapers and sickles of native workmanship occur: but under the XVIII. dynasty, after another period of eclipse, bronze is found to have superseded flint. Flint implements, however, of a coarser kind, continued to be used as late as the fourth century A.D.

Metal-working is first found under the III. dynasty, and copper tools are habitually used under the IV. for mason's work; copper needles were also in use. Only one sample of bronze is known of this age; the rest are of pure copper. The "New Race," though devoted to stonework, produced occasional fine copper implements; one notable dagger is of an "Ægean" type. Under XII. dynasty, copper is still predominant, and much commoner; tempered with copper oxide and with arsenic. Bronze begins with XVIII. dynasty. Silver and gold are well worked from an early period; almost absent from "New Race" graves, which, however, seem to have been rifled. Iron has not been found earlier than foreign, mostly Greek deposits of XXVI. dynasty (650-550 B.C.). Earlier supposed allusions to "iron" in inscriptions really refer to "bronze."

Mr. H. Swainson Cowper gave a lantern lecture on the Senams, or megalithic monuments of Tripoli, of which he has visited nearly sixty. Rectangular enclosures of good masonry are associated with trilithons like those of Stonehenge, but with very narrow apertures between the jambs; the height varies from 6 to 15 feet. They are erected on footing stones, and are apparently designed to hold additional superstructures of wood. The forms of the stones themselves also sometimes recall carpentry types, which in so treeless a country are remarkable. A massive stone altar, often grooved, and level with the ground, sometimes stands in front of a trilithon. The few sculptures associated with the Senams are of Roman style, with Phallic subjects; but are not necessarily contemporary with the monuments themselves. The Senams appear to have been objects of worship, and usually stand upon hill-tops. Mr. Swainson Cowper suggests that they are analogous to the "Asherah" of the Old Testament, and to similar structures represented on Babylonian cylinders.

Mr. W. J. Lewis Abbott sent a report on the Hastings kitchen midden. The fissures in the sandstone cliffs at Hastings have been used as dwellings in Neolithic times, and the refuse, containing numerous flakes, implements, and fragments of pottery, has accumulated in front of their openings.

Saturday.—Ethnology.—The tenth report of the Committee on the North-Western Tribes of Canada was presented. This Committee was appointed at the Montreal Meeting 1884, and has published, hitherto, the following important memoirs in its reports to the British Association:

Introduction (Report VII.). Sir Daniel Wilson.
Circular of Inquiry (III.).
North American Ethnology (V.). Mr. Horatio Hale.
Linguistic Ethnology (VIII.). Mr. Horatio Hale.
Physical Characteristics (VII.). Dr. Franz Boas.
The Blackfoot Indians (I.). Mr. Horatio Hale.
The Blackfoot Indians (II.). Rev. E. F. Wilson.
The Sarcee Indians (IV.). Rev. E. F. Wilson.
The Kootenay Indians (VIII.). Dr. A. F. Chamberlain.
Ethnology of British Columbia (V.). Mr. Horatio Hale.
Notes on Indians of British Columbia (IV.). Dr. Franz Boas.
Reports on Indians of British Columbia (V.-X.). Dr. Franz Boas.

The report now presented contains a further account of the physical characteristics of the tribes of the North Pacific Coast; notes on the Tinneh Tribe of Nicola Valley, by Mr. James Teit; on the Tinneh Tribe of Portland Canal, and on the Nass River Indians, by Dr. Boas; and the grammar and vocabulary of the Nisk·â and Tsetsâ'ut languages.

Much, however, remains to be done in order to give a satisfactory review of the anthropology, even of British Columbia: in particular, the influence of the tribes of Millbank Sound on their neighbours; the highly developed art of the Haida, and the complicated symbolic and conventional ornaments; and the peculiar distribution of physical types need further elucidation.

The Committee has accordingly been reappointed with a grant of £100, in order to enable Dr. Boas to continue his important investigations.

Captain S. L. Hinde read a paper on the cannibal tribes of

the Congo. Cannibalism is in his experience in this region almost universal, on the increase, and peculiarly inveterate. An extensive traffic in human flesh prevails, and slaves as well as prisoners are kept and sold for food. Even corpses are disinterred in spite of charms on the graves: the flesh is always cooked or smoked, but is not here eaten from any religious or superstitious motive. The practice of filing the front teeth is not found to be coextensive with that of cannibalism.

Mr. Darnell Davis derived the name "cannibal" from the Caribs of the West Indies, who, however, are not man-eaters; Mr. Elworthy discussed the theory of cannibalism as a means to acquire the properties of the thing eaten; and Mr. Hartland the survivals, in Europe, of ceremonial and sepulchral cannibalism.

Captain Hinde also described the pigmies of Central Africa, nomadic hunters, of less than four feet stature.

Mr. A. Montefiore gave an account of the Samoyads of the Arctic Tundras.

Reports were presented by the Committees on physical deviations of children from the normal, and on anthropometric measurements in schools.

The anthropometric laboratory, which is usually organised during meetings of the Association, was not this year available.

On Monday, Mr. Elworthy read a paper on horns of honour, dishonour, and safety. The head is the object of honour, and is adorned with symbolic attributes. Horns are symbolic of the crescent-goddess: so of divine power, protection and favour in general. Conversely, to "scorn" (French *écorner*) is to deprive of such horns and prestige. The paper gave rise to some comment. Not all horns are crescent-symbols: most were originally worn attached to skins; ornaments are decorative first, symbolic afterwards.

Mrs. Grove discussed the religious origin of dances, as forms of magic or worship. Weapon-dances arise from worship of weapons, or of an armed deity: ritual dances from the love of dancing attributed to the deity, and as the expression of exalted enthusiasm; funeral dances propitiate either death, or the departed soul. As civilisation advances, the expressions of emotion are restrained, and dances lose their meaning and popularity.

The report of the Ethnographic Survey of the United Kingdom was read by Mr. Hartland, who was followed by Mr. J. Gray with observations specially relating to East Aberdeenshire, and by Dr. Garson with similar results from Suffolk. Work has also been begun in Hertfordshire and East Anglia (by the Cambridge Sub-Committee), and is projected in Galloway, and in Caithness, Elgin, and Nairn, by Dr. Walter Gregor.

Mr. C. G. de Betham read a fully illustrated paper on the peculiarities of the Suffolk dialect, which retains an unusual number of Anglo-Saxon idioms; and on the proverbs, traditions, and folk-medicine of the district. Mr. Lingwood exhibited two young ash-trees from Needham Market, which had been split in order to pass sick children through the stem.

Mr. Clodd read a paper on the objects and method of the study of folk-lore, which was followed by a lantern lecture by Prof. A. C. Haddon, on the same subject, exhibiting a series of persons, trees, wells, and other natural objects and prehistoric monuments to which traditions are attached, and illustrating a number of games and ceremonies, in which primitive beliefs and practices are perpetuated.

On Tuesday a formal discussion took place on the results of interference with the civilisation of native races. The subject was briefly introduced by the President, and papers were contributed by Lord Stanmore, Prof. A. C. Haddon (New Guinea), Dr. Cust (India), Dr. H. O. Forbes (Dutch East Indies), Messrs. E. Im Thurm and Darnell Davis (British Guiana), Ling Roth (Tasmania and Australia), and Raynbird (Central India). The course of the debate was summed up by the President as follows. The principle of government should be to protect the natives against their own weakness, the evil influences of debt, and the loss of their land. Rigorous impartiality may be the greatest injustice to the natives, and it is only by dealing with them from their own sense of justice that influence can be obtained. Native customs should not be unnecessarily interfered with, and then only with careful attention to the native point of view. Laws of morality differ in various countries, and what is "right" here is "wrong" there. Changes of detail should be left to the change of native opinion, rather than be enforced by law. It is, for instance, as cruel and disastrous to dress a native of a jungle in our tight, ill-ventilated clothes, as to expose an European naked in a tropical climate. With regard to education, opinions seem to differ; the completely savage brain cannot acquire our ways of thought suddenly without excessive strain and enfeeblement; but native races differ very widely in receptivity and imitativeness. What is above all things necessary is that sympathy of fellow-feeling which at once places one man on an easy and equal footing with another, and which savage races are very quick to perceive and reciprocate.

Rev. Hartwell Jones followed with a philological contribution to the history of primitive warfare in Greece and Italy.

Dr. Garson described a skull found in Thames Valley gravel, which contains palæolithic implements, and claimed it as palæolithic on morphological grounds; supported by Mr. Stopes. Sir John Evans, Prof. Boyd Dawkins, and Mr. Myres disputed the attribution.

A large collection was exhibited of photographs illustrative of the Andamanese and their civilisation, sent by Mr. Maurice Portman.

On Wednesday, Dr. Munro gave a fully illustrated lantern lecture on the newly discovered Neolithic settlement at Butmir in Bosnia. Flint and jasper weapons were manufactured in great variety on the spot, while polished hammers and axes were brought from a distance; and black pottery, with elaborate incised angular ornaments, was extensively made. A principal feature in the site is the occurrence of irregular depressions in the basal clay below the débris. Continental observers considered these to be the floors of huts; but Signor Pigorini and Dr. Munro found traces of piles, and argued that the houses were pile-dwellings, and that the hollows were made to obtain clay for wattle-work and pottery. Sir John Evans supported the pile-dwelling theory, and suggested that dredging might explain the irregularity of the hollows.

Mr. A. J. Evans described a series of primitive European idols, with diagrams and exhibits. Beginning with the marble images of the Greek archipelago, he sketched the area over which kindred figures occur, in Italy, Sicily, Spain, Liguria; and thence into Central Europe and the shores of the Baltic, and even as far as Orkney. The Oriental origin of these figures, formerly maintained, is now strongly contested: they probably testify to an indigenous practice of burying at first actual, and subsequently substituted attendants with deceased persons. Prof. Petrie compared the Maltese seated figures with those of the "New Race" in Egypt.

Dr. Munro presented a further report on the Lake Village of Glastonbury. Amongst the relics found were examples of pottery which were, undoubtedly, highly ornamented specimens of late Celtic art. Other articles unearthed must have been imported two or three centuries before the Roman occupation. Prof. Boyd Dawkins regarded the evidence as conclusive that the Lake Village of Glastonbury might be dated from 200 B.C. to the time of the Roman occupation.

Mr. Theodore Bent contributed a paper on the natives of Southern Arabia.

The Section was closed with a hearty vote of thanks to the President.

MECHANICS AT THE BRITISH ASSOCIATION.

SECTION G, which is devoted to mechanical science, had an unusually heavy programme at the late Ipswich meeting; indeed it was rather too heavy for the majority of members, for often the proceedings were carried on before a very scanty audience. It is a question whether, in this Section at any rate, a good deal of judicious weeding could not be done. Of course it is understood that "mechanical science" shall be translated as engineering in general—and that is a very good thing, as otherwise many good papers on what is generally known as "civil engineering" would be shut out from the Association altogether but with a most benevolent desire to give all branches of applied science a hearing, one cannot help thinking it would be an advantage to every one concerned especially the authors—if some proffered contributions were returned with thanks. The fact is, an exercise of the selective faculty, and perhaps a little more callousness to the demands made by the sensitiveness of authors, would do much towards rendering the proceedings in Section G more bearable than they have been for some time past.

There was, however, a good deal that was interesting and distinctly valuable in the proceedings of the Section at this year's meeting. The pity was that it should have been often wasted

on an all but empty room. Another cause of complaint on the part of members of this Section was that the second Wednesday was a *dies non*. Doubtless very few object to a whole holiday at these meetings, but what people do find fault with is that they should be kept hard at work on Saturday, when there are pleasant excursions, to be turned adrift on Wednesday. Of course one can go home and cut the business short, and that is what many do, and the Thursday's excursions thus suffer. Indeed a conscientious member, determined to do his Section G thoroughly, was unable to go to any of Saturday's excursions, and would have to spend an idle day waiting for the Thursday's excursions. The excursions are the great feature of the Association meetings, as they bring members together and make them known to each other in a way that no other institution or society does. Possibly more has been done for the Advancement of Science by such means than by the meetings of Sections, for there are other associations which afford opportunities for the reading and discussion of papers, but none which offer the same social facilities as the British Association. When it is remembered that only two Sections met on the second Wednesday, it is a question whether it would not be of advantage to make it a rule to fix the whole day excursions for Wednesday instead of Thursday. We are aware that this would create difficulties in regard to meetings of general committees, but surely these could be overcome.

The President of Section G this year was Prof. L. F. Vernon-Harcourt, who opened the proceedings of the Section by reading his presidential address.

The first paper taken was a contribution by Major-General Webber, on light railways as an assistance to agriculture. It contained the main elements of a scheme which the author had thought out for introducing a system of light railways in Suffolk. A good deal of attention was given to the subject of gauge, which the author considered should be narrower than the standard gauge of the country, viz. 4 ft. 8½ in. There is much to be said in favour of a narrow gauge for auxiliary railways, but also much to be said against it. No doubt a narrow gauge is cheaper than a wider one, but perhaps not so much cheaper as many persons imagine. Sharper curves can also be taken with a narrow gauge, and it can be laid in position where often the broader gauge would necessitate the widening of the road. On the other hand, the standard gauge enables the waggons and trucks of the trunk lines to be run on the auxiliary railways. It may be said that a light railway demands—on the score of cheapness—that the road bed shall be of a less substantial character than that of the trunk lines; but here it is essential to bear one fact in mind. The massive permanent way of our trunk lines is required for the heavy locomotives running at high speed. With small engines and comparatively slow speed very light permanent way will carry the ordinary railway goods stock with safety. The first thing, however, which has to be done in order to facilitate the introduction of auxiliary railways in this country, is to give power to the Board of Trade to relax its own regulations.

A paper by M. A. Gobert, of Brussels, on a freezing process for shaft-sinking, was next read. In general principle the suggestion is not new. In cases where water-bearing strata is encountered in shaft-sinking, a freezing medium is caused to [illegible] in pipes. The vehicle used is ammonia, which, evaporating in the pipes, produces the freezing effect.

The next paper read was of considerable interest; it was a [illegible] by Mr. W. H. Wheeler, of Boston, on the effect of [illegible] atmospheric pressure on the tides. For many years past [illegible] has been making observations on this subject. From [illegible] of two years' tides at the Port of Boston, (excluding [illegible] when the element of wind would affect the case), he found that out of 152 observations, 61 gave results opposite [illegible] which would have been expected by the readings of the [illegible] alone; for a high barometer was frequently [illegible] by a high tide, and a low barometer by [illegible]. On the other hand it was found, with few [illegible] that when the wind blows with any force along [illegible] the same direction as the main stream of the [illegible] at all the ports along the coast will be [illegible] height given in the tide tables; and [illegible] against the flood tide, high water will be [illegible]. [illegible] to figures quoted in the [illegible] effect of wind [illegible] as to affect the tide as [illegible] 5 to 6 feet and a difference of as much as 8 [illegible] been observed between two succeeding tides. An analysis of the register of tides at Boston Dock for two years showed that 24 per cent. of the whole tides recorded were sufficiently affected by the wind to vary 6 inches from the calculated height. Thirty varied by 2 feet, seven by 3 feet, six by 3½ feet, three by 4 feet, two by 4½ feet, one by over 5 feet, and one by 6 feet 3 inches. From the observations he has made, Mr. Wheeler has deduced the approximate rule that with a given force of wind of 3 on the Beaufort scale a tide will be raised or depressed by half an inch for every foot of range. With a force of from 4 to 6, the variation may be expected to be 1 inch for every foot, with a gale from 7 to 8 it will be 1½ inches, and if the gale increases to 10 it will be 2 inches. It will be seen that the subject is one which possesses not only scientific interest, but considerable practical importance to mariners; and so far as we are aware, Mr. Wheeler is the first who has obtained quantitative results of this nature. In the discussion which followed, it was pointed out that the time element would have to be given its due value.

At the second sitting of the Section, on Friday, the 13th ult., Mr. G. J. Symons gave what was really a lecture on the autumn floods of 1894. This contribution was discussed together with a paper by Messrs. Rapier and Stoney, on weirs in rivers. Any contribution by Mr. Symons is sure to meet with a good reception at a meeting of the Association, and Mr. Stoney's work in connection with river engineering is also so well known, that it was not surprising that the attendance in the Section should be a full one when the sitting opened. The floods of November of last year, it will be remembered, were of an unusually severe character, a great part of the low-lying lands of the Thames Valley being submerged. The meteorological conditions which led to these floods were traced by Mr. Symons, and the effects stated. With regard to the latter, it would be but to repeat a long history of flooded homes, spoiled furniture, and general damage to property. The extent of course will never be known, but it was sufficient to be accounted a calamity of considerable magnitude. There were two periods of heavy rainfall quickly succeeding each other, but it was the second which was the immediate cause of damage; the first, if it had stood alone, would have been comparatively innocuous. The first period occurred at the end of October, and nearly all the additional land water caused by it had passed over Teddington Weir before the second period arrived. The November rains, however, found the earth well saturated, and the water that fell ran therefore almost wholly into the river bed, with the unfortunate results before referred to. The moral Mr. Symons chiefly strove to impress was the necessity of automatic records and communication between different divisions of a water shed, so that prompt warning might be given of a probable flood. Such precautions are taken by continental nations, but in England they are sadly neglected. The necessity for obtaining accurate data, and treating it in a systematic and scientific manner by trained observers, was well illustrated by instances given; for example, the river Mole was at its highest four days before the Thames, and if the warning thus given by nature had been heeded, much of the damage which followed might have been prevented.

The second paper gave a good description of the movable weirs which have become identified with Mr. Stoney's name, and which were so prominently brought before public notice in connection with the Manchester Ship Canal. A more recent example, and one which is better known to Londoners, is that at Richmond, where there is a half-tide lock and a series of lifting weirs. It has been claimed that if many of the fixed weirs in the Thames were removed, and these lifting weirs substituted for them, that there would be less danger from flooding of the river. How far Messrs. Rapier and Stoney go in this direction we did not gather from the paper, but such we took to be the general drift of their argument. The position was disputed during the discussion which followed, it being maintained by some speakers that even if the flow of water were absolutely unimpeded as far as Teddington Weir, the tidal portion of the river-channel is not of sufficient section to carry off all water that comes down in time of heaviest rainfall. The question is complicated by the ebb and flow of the tide, but it ought not to be impossible to arrive at a fairly definite conclusion. The matter is one which wants investigation by a competent authority, for we did not notice that any more than general statements were made in support of the alleged insufficiency of the tidal channel; and the statements, therefore, did not appear to rest on a substantial basis of fact. The problem of the utilisation of the head of water at the weirs in the Thames was also brought forward. Without

going into details, it may be said that the discussion tended to show that there is little probability of any useful work being done in this direction unless some entirely new departure in the construction of turbines be discovered. Mr. Stoney, however, in his reply to the discussion, gave a sketch of a very ingenious device by which he proposed to increase the available head in the case of its diminution by the rise of water in a river. We think, however, that something more than this will be needed before the Thames weirs become commercially successful as a source of power.

Dr. Anderson described a rotating fan he had devised, to be used in place of bellows for organ-blowing. The application was successful, as might be supposed in the case where a volume of air, large in comparison with its velocity, was required to be set in motion. A paper by Mr. Birt, on the growth of the port of Harwich, was interesting from a commercial and economic point of view, and may be taken in conjunction with a note by the President, on the Hook of Holland route.

A description of a railway up Snowdon, which is in course of construction, brought the proceedings of the day to a close.

On Saturday the proceedings commenced with the presentation of two reports by Committees of the Section: the first on standardising, and the second on coast erosion. The standardising report was of an interim character, and does not require extended notice, in prospect of being brought forward again. The coast erosion report was also presented in another Section. Mr. A. G. Lyster gave a long description of the dredging operations now going on at the mouth of the Mersey to reduce the bar which has too long been allowed to impede the navigation of our great Atlantic port.

A paper by Mr. E. Hesketh, describing a process of refrigerating by carbonic anhydride, was next taken. This was a very interesting contribution, and afforded a good example of the type of paper that should be presented to the Section. It does not, however, lend itself very easily to our present purpose, as it consisted mainly of details of construction of the machinery, which, though highly interesting, it would be impossible for us to make clear without the many illustrations by which the author explained his meaning. Another good and characteristic paper was contributed by Mr. J. Napier, who described an installation that has been carried out at Ipswich of the Hermite process of purifying sewage. Briefly stated, the process consists of passing an electric current through sea water. A part of the chlorides is converted into hypochlorite, and a deodorising agent is thus obtained. The electrolysed water is passed into the drains or sewers. The system, if worked to the full extent, as proposed by the inventor, would consist of having a separate service of the electrolysed water laid on for use in closets, house drains, &c. The system has been in use but a short time in Ipswich, and is said to promise very favourably by those who have been connected with its working.

The Monday of the meeting is always devoted by Section G to electrical engineering, and at the recent meeting the proceedings on that day, the 16th ult., were opened by a long paper from the pen of Mr. Philip Dawson, on the modern application of electricity to traction purposes. Mr. Dawson has evidently travelled much in the United States, and has there collected a vast amount of data bearing on the subject of his paper. To attempt to follow him into the details he gave in his paper would be hopeless in this report. He is a strong advocate of the trolley system of transmission, holding that it will supersede all others; and indeed experience in America goes far to bear him out in this. It is needless here to point out how great has been the progress made in the United States in tramway propulsion by electricity; but one fact stated at the meeting may be repeated, as it puts the whole matter very forcibly. It was said that it is becoming a great problem what is to be done with the horses that are being pushed out of the field by electricity. In some places they are being killed for the sake of their hides and tallow; whilst in other districts good horses were to be bought at two dollars each. The latter figure we think may be open to question, for surely a dead horse is worth more than two dollars. However, there is no doubt that electric traction has made immense strides in America, and has in great cities practically supplanted not only the horse and mule, but is fast edging out its mechanical rivals the cable and steam engine.

The next item on the agenda was a paper by Messrs. Preece and Trotter, on an improved portable photometer. This paper was listened to with great interest; Mr. Trotter illustrating his remarks by examples of the different forms and apparatus he had devised for street work. The paper began by a definition of what is meant by illumination. When light falls upon a surface, that surface is said to be illuminated. The illumination depends simply upon the light falling on the surface, and has nothing to do with the reflecting power of the surface, just as rainfall is independent of the nature of the soil. It depends also on the cosine of the angle of incidence. The lighting of streets and of buildings may be specified by the maximum and minimum illumination. The primary purpose of an illumination photometer is to measure the resulting illumination produced by any arrangements of lamps irrespective of their number, their height, or their candle-power. The instrument under notice consisted of a box, on the upper surface of which is a diaphragm of white card painted with a whitewash of magnesia and isinglass. It has one or more star-shaped perforations. Immediately below it, within the box, is a white screen capable of adjustment at different angles and two small electric lamps of different candle-power, either or both of which can be used. A portable secondary battery is used to supply them with current. The illumination of the hinged screen inside the box varies approximately as the cosine of the angle of incidence of the light from the electric lamps upon it. A handle with a pointer moving over a graduated scale is connected to the screen with a system of levers, and the inclination is so adjusted that the illumination of the screen is equal to that of the perforated diaphragm, the perforations seeming to disappear when this balance is affected. The illumination can then be read off on the scale in units of the illumination due to one standard candle at one foot distance. The object of the levers is to give an open and convenient scale. The scale is graduated by experiment, and does not depend upon the the cosine law. The colour difficulty, where arc light or daylight is to be measured, is reduced by the use of a yellow tinted diaphragm and a blue-tinted screen, the tints being selected so that the readings are the same as the mean of a large number of measurements made with white screens. By means of a graduated quadrant and a gnomon the angle and the cosine of the angle of incidence of the light from a lamp may be measured. Rules are given for deducing the height of the lamp and the slant height, and hence the candle-power of the lamp.

The discussion on this paper was of a very brief nature, and elicited no new facts of importance.

Mr. H. A. Earle read a paper on storage batteries, dealing chiefly with the chloride battery which has lately been introduced, and which, it is claimed, possesses the advantages of other and earlier types without many of the attendant disadvantages, chiefly from the fact that an oxide paste is not used. A mixture of chloride of lead and chloride of zinc is cast into small tablets, which have cast round them at high pressure a frame of antimonious lead. The subsequent elimination of the chloride and zinc leaves a porous structure of pure lead of a crystalline nature, good conductivity, and with a large surface exposed to the electrolyte. The result is a large capacity for a given weight and space occupied.

At the last sitting of the Section, held on Tuesday, the 17th ult., nine papers were read and discussed. We must deal with these very briefly. The first was by Mr. P. V. Luke, and was entitled "the field telegraph in the Chitral campaign." It was of a popular nature, and was illustrated by magic lantern. Mr. G. Johnstone Stoney explained, by the aid of the apparatus itself, a movement designed to attain astronomical accuracy in the motion of siderostats. Without the aid of diagrams it would not be possible to explain the mechanism, and we will leave it therefore for the present. A paper by Mr. F. W. Turner explained the modern process of preparing flour from the wheat berry by means of metal rollers in place of the old millstones. The paper was very interesting and treated the whole subject throughout, illustrations of the various machines used being hung on the walls. Mr. J. Southward gave an interesting description of the Linotype process of printing, describing in detail and by the aid of illustrations the really wonderful machine which has been devised for the purpose. Mr. R. E. Crompton, in a memorandum on the B. A. screw gauge for small screws, pointed out the advantage that would follow if complete uniformity were observed among manufacturers in this matter, and dwelt on the desirability of a standard plate being provided for the purpose by the Board of Trade. Mr. John Key contributed a paper describing the differences in the practice of English and foreign Government departments and registration societies in their

requirements for the provision for safety in marine boilers and engines. The want of uniformity here again is undoubted.

Lieut. B. Baden-Powell described a means he suggested for navigating the air by means of kites. He pointed out that as greater height above the surface of the earth is reached, the wind nearly always increases in force. At 1000 yards it often blows at three times the velocity that it does near the surface. He proposes to take advantage of this difference by sending one kite to the upper atmosphere, and keeping another nearer the ground. The two kites would be connected by a long line, and the weight to be carried would be attached to the line at a point nearer to the lower kite than to the higher. The lower kite would thus supply a retarding medium to the upper, so that the effect would be the same in principle, though not in degree, as if the upper kite were held to the earth by a string, and the lower kite were towed through the air by a boy running with the string in his hand. By the forces thus brought to bear both kites would be kept flying although not held to the earth by a string in the usual way, and it is thought that possibly they might be navigated in directions other than that in which the wind might be blowing. It will be seen that the author depends on the difference in velocity of currents of air at two heights; and were this difference to fail, or to become insufficient, the experimenter would come to the ground. This might prove awkward unless a clear field were provided for the descent. The suggestion however is ingenious, and no doubt many persons interested in the problem of aerial navigation would be pleased to see the author put his theories to the test of practice.

The last paper presented at the meeting was a contribution by Prof. A. E. Elliott, of Cardiff, on receiver and condenser drop. It is a subject that deserves far more consideration and discussion by members of the Section than they were able to give on hearing it read rapidly at the end of the meeting. Papers of this nature should be read at one meeting, and the discussions adjourned until another; or perhaps it would be better to distribute them two or three months before the meeting, and dispense with reading altogether. A joint meeting of Sections A and G would afford the appropriate audience for considering the subject of Prof. Elliott's memoir.

BOTANY AT THE BRITISH ASSOCIATION.

THE President (Mr. Thiselton-Dyer) exhibited photographs and specimens of a large cedar (*Cedrus Deodara*, Loud.) from Kew, which had been struck and completely shattered by lightning on August 10. It was pointed out that the main stem had been in part blown into matchwood by the violence of the shock, and branches were torn off with large portions of the trunk adhering to their base. Prof. Oliver Lodge took part in the discussion as to the probable explanation of the unusual nature of the explosion, which seemed to have been centrifugal, the stem having been disrupted from the centre, and not merely stripped superficially.

Prof. Bretland Farmer described a set of wax models illustrating the typical forms passed through, and the chief variations exhibited, by the chromosomes during the division of the nucleus in the spore-mother cells of plants. The wax employed is made of a mixture of one part of white wax, with five parts of paraffin, the melting point of which is about 50° C.

THALLOPHYTA.

Experimental studies in the variation of yeast cells, by Dr. Emil Chr. Hansen (Copenhagen). The author gave an account of his earlier and more recent investigations. Among the latter he especially dwelt on those in which, by one treatment, varieties were produced that gave more, and by another treatment less, alcohol than their parent cells. He pointed out that the observed variations could be grouped under certain rules. From his researches on the agencies and causes to which variation is due, he found that temperature was the most influential external factor.[1]

A false *bacterium*, by Prof. Marshall Ward, F.R.S.

On the formation of bacterial colonies, by Prof. Marshall Ward, F.R.S.

On the structure of bacterial cells, by Harold Wager. In this paper an account was given of the present state of our knowledge of the cells of bacteria. Reference was made to the observations of Schottelius, Migula, De Bary, Bütschli, and others. The author showed that it is possible to demonstrate in the majority of bacterial cells the presence of two substances, one of which may be regarded as protoplasmic in nature, and a second, which stains deeply when acted upon by fuchsin and kindred staining substances, and which may be regarded as nuclear. It was pointed out that this nuclear substance does not possess the structure of nuclei in the cells of higher plants.

Note on the occurrence in New Zealand of two forms of Peltoid *Trentepohliaceae*, and their relation to the lichen *Strigula*, by A. Vaughan Jennings. The *Trentepohliaceae* which form epiphyllous cell-plates are at present known only from the tropics. They have been recorded from South America, India, Ceylon, and the East Indies, but not up to the present time from New Zealand. The author gave a summary of previous literature, and described two forms found by himself in New Zealand. (1) *Phycopeltis expansa*, sp. nov. This species forms wide-spreading yellow cell-plates on the leaves of *Nesodaphne*; it bears two kinds of sporangia, and is often associated with brown fungus hyphæ growing between the cell rows, but not affecting the growth of the alga. On the other hand, when attacked by different hyphæ, the result is the formation of the lichen *Strigula*, which in Ceylon was shown by Ward to have for its algal element *Mycoidea parasitica*, Cunn. (2) *Phycopeltis nigra*, sp. nov. On leaves of *Nesodaphne* and fronds of *Asplenium falcatum*. Two distinct varieties of this species were described. The plant is never attacked by fungus hyphæ, and never takes any part in lichen formation, even when on the same leaf with *Phycopeltis expansa* and the associated *Strigula*.

BRYOPHYTA AND PTERIDOPHYTA.

On a supposed case of symbiosis in *Tetraplodon*, by Prof. F. E. Weiss. The author exhibited specimens of *Tetraplodon* from the Cuchullin Hills in Skye, where it was found plentifully on animal excreta. In September he found many of the patches mixed with an orange-coloured *Peziza*, which did not appear to have in any way injured the moss plants. The rhizoids of the moss, however, contained in many cases fungal hyphæ closely resembling those of the *Peziza*, and though present in the cells of the moss, these latter did not seem to be injured by them. He suggested that this might be an instance of symbiosis; the moss, as in the case of other green plants, making use of the fungal hyphæ to obtain its nutriment from the organic material. The ultimate proof of such a case of symbiosis would, however, necessarily depend upon culture experiments, which he understood were now being made by another observer.

Remarks on the Archesporium, by Prof. F. O. Bower, F.R.S. Prof. Bower pointed out that the recognition of the archesporium as consistently of hypodermal origin cannot be upheld, and quoted as exceptions *Equisetum*, *Isoetes*, *Ophioglossum*, and especially the leptosporangiate ferns. He laid down the general principle that the sporangia, as regards their development, should be studied in the light of a knowledge of the apical meristems of the plants in question. Where the apical meristems are stratified, the archesporium is hypodermal in the usual sense; where initial cells occur, the archesporium is derived by periclinal divisions of superficial cells. Intermediate types of meristem show an intermediate type of origin of the archesporium. He cited as an illustrative case that of *Ophioglossum*, admitting that the hypodermal band of potential archesporium, which he had previously described, does not occur always or in all species. But so far from thus giving up the case for a comparison with *Lycopodium*, he holds that as *Ophioglossum* has a single initial cell in stem and root, it would be contrary to experience to expect or demand a hypodermal archesporium. (The details will shortly be published elsewhere, with illustrations.)

On the prothallus and embryo of *Danæa*, by G. Brebner. Mr. Brebner gave an account of the prothallus and sexual organs of *Danæa simplicifolia*, Rudge, as the result of investigations made on some material from the Botanic Gardens in British Guiana. He pointed out that there is a close similarity between the *Danæa* and the other two genera of the *Marattiaceæ*, *Angiopteris* and *Marattia*, of which the prothallus has been previously described. An interesting fact was noted as regards the prothallus rhizoids, which possess a distinctly septate structure, and so far resemble a moss protonema. Possibly similar septate rhizoids may be found in the other marattiaceous genera. The development of the antheridia of *Danæa* agrees in the main with that in *Marattia* and *Angiopteris*:

[1] A [illegible] of Dr. Hansen's work will be published in the *Annals of Botany*.

the material did not allow of any developmental study of the archegonia. The concentric bundle of the primary embryonic stem shows an endodermal layer. On the whole the author found in *Danæa* a complete agreement, in all essential features, with *Angiopteris* and *Marattia*, as regards prothallus, reproductive organs, and embryo development.

PHYSIOLOGY, &c.

The localisation, the transport and *rôle* of hydroycanic acid in *Pangium edule*, Reinw., by Dr. M. Treub (Buitenzorg, Java).—Five years ago Dr. Greshoff made the remarkable discovery that the poisonous substance contained in great quantities in all the parts of *Pangium edule*, was nothing else than hydrocyanic acid. This interesting chemical discovery was the starting-point of Dr. Treub's physiological investigations. In microchemical researches hydrocyanic acid presents a considerable advantage as compared with the great majority of substances to be detected in tissues by reagents; namely, that the Prussian blue reaction, easily applicable in microchemical research, gives completely trustworthy results. The appearance of Prussian blue in a cell may be accepted as certain proof of the previous occurrence in the cell of hydrocyanic acid, no other substance producing the same reaction. The leaves prove to be the chief factories of hydrocyanic acid in *Pangium*, though there are other much smaller local factories of this substance in the tissues of other organs. The hydrocyanic acid formed in the leaves is conducted through the leaf-stalks to the stem, and distributed to the spots where plastic material is wanted. The acid travels in the phloem of the fibro-vascular bundles. Dr. Treub regards the hydrocyanic acid in *Pangium edule* as one of the first plastic materials for building up proteids; he thinks it is, in this plant, the first detectable, and perhaps the first formed product of the assimilation of inorganic nitrogen. In accordance with this hypothesis, the formation of hydrocyanic acid in *Pangium* depends, on the one hand, on the presence of carbo-hydrates or analogous products of the carbon-assimilation, and, on the other hand, on the presence of nitrates. These two points were proved, or at least rendered acceptable, by a great number of experiments made by Dr. Treub in the Buitenzorg Gardens. (The details of this investigation will be found in a paper appearing in the forthcoming number of the *Annales de iardin botanique de Buitenzorg*.)

On the diurnal variation in the amount of diastase in foliage leaves, by Prof. Reynolds Green, F.R.S. The diastase which is present in foliage leaves varies in amount during the day, being greatest in the early morning, and least after sunset. The cause of the variation has been ascertained to be chiefly, if not entirely, due to the action of the sunlight. The author showed last year, at the Oxford meeting, that diastatic extracts exposed to sunlight or electric light, without the interposition of any form of screen, have their activity largely impaired, the damage amounting sometimes to 70 per cent. Experiments made upon the living leaf of the scarlet-runner showed a similar destructive action of the light, the amount of destruction only amounting, however, to about 10 to 20 per cent. The author attributes this difference to the screening action of the proteids in the cells of the leaf.

On cross and self fertilisation, with special reference to pollen prepotency, by J. C. Willis. The time has passed for regarding self-fertilisation as being always necessarily harmful in itself, and it is now recognised as a regular feature in the life-history of many plants. There are many species of plants in which both self and cross pollination occur nearly, or quite, simultaneously, and it is very desirable to know what happens in these cases. Darwin's experiments render it probable that prepotency of foreign pollen is usual. The author's experiments have been devoted to a study of the relative chemical attraction of "own" and "foreign" pollen by the same stigma (chiefly in gelatine and agar cultures), and have given negative results. It seems probable, putting together all the various known facts, that prepotency, where it occurs, is due to actions set up after the pollen tubes have entered the stigma, these actions tending to favour the growth of the "foreign" pollen-tubes, and to check that of the "own" pollen.

PALÆOBOTANY.

The chief results of Williamson's work on the Carboniferous plants, by Dr. D. H. Scott, F.R.S. The origin and history of the late Prof. Williamson's researches on the Carboniferous flora were briefly traced. His great work, chiefly, though not entirely, contained in his long series of memoirs in the *Philosophical Transactions* of the Royal Society, consisted in thoroughly elucidating the structure of British fossil plants of the Coal period, and thus determining, on a sound basis, the main lines of their affinities.

Four of the principal types investigated by Williamson were selected for illustration the *Calamarieæ*, the *Sphenophylleæ*, the *Lyginodendreæ*, and the *Lycopodiaceæ*.

(1) The *Calamarieæ*.—Williamson's great aim, which he kept in view all through, was to demonstrate the essential unity of type of the British Calamites, *i.e.* that they are all Cryptogams, of equisetaceous affinities (though sometimes heterosporous), but possessing precisely the same mode of growth in thickness by means of a cambium, which is now characteristic of Dicotyledons and Gymnosperms. His researches have given us a fairly complete knowledge of the organisation of these arborescent Horse-tails.

(2) The *Sphenophylleæ*, a remarkable group of vascular Cryptogams, unrepresented among living plants, but having certain characters in common both with *Lycopodiaceæ* and *Equisetaceæ*, are now very thoroughly known, owing, in a great degree, to Williamson's investigations. The discovery of the structure of the fructification, absolutely unique among Cryptogams, was in the first instance entirely his own.

(3) The *Lyginodendreæ*.—The existence of this family, which consists of plants with the foliage of ferns, but with stems and roots which recall those of Cycads, was revealed by Williamson. This appears to be the most striking case of an intermediate group yet found among fossil plants.

(4) The *Lycopodiaceæ*.—Williamson added enormously to our knowledge of this great family, and proved conclusively that *Sigillaria* and *Lepidodendron* are essentialy similar in structure, both genera, as well as their allies, being true Lycopodiaceous Cryptogams, but with secondary growth in almost all cases. He demonstrated the relation between the vegetative organs and the fructification in many of these plants, and by his researches on *Stigmaria*, made known the structure of their subterranean parts. The different types of *Lepidodendron*, of which he investigated the structure, were so numerous, as to place our knowledge of these plants on a broad and secure foundation. (The paper was illustrated by lantern-slides, partly from Williamson's figures, and partly original.)

On a new form of fructification in *Sphenophyllum*, by Gra Solms-Laubach (Strassburg). Graf Solms gave a brief sketch of the history of our knowledge of the fructification of the Carboniferous genus *Sphenophyllum*. He described the type of strobilus originally named by Williamson *Volkmannia Dawsoni*, and subsequently placed by Weiss in the genus *Bowmanites*; this fructification has recently been shown by Williamson and Zeiller to belong to *Sphenophyllum*. The author proceeded to give an account of a new form of strobilus recently obtained from rocks of Culm age in Silesia; this shows certain important deviations from the fructifications previously examined. In the *Sphenophyllum* strobili from the Coal-Measures the axis bears successive verticils of coherent bracts, the sporangia are borne singly at the end of long pedicels twice as numerous as the bracts, and arising from the upper surface of the coherent disc near the axil. In the Culm species, *Sphenophyllum Römeri*, sp. nov., the bracts of successive whorls are superposed and not alternate, as described by other writers, in the Coal-Measure species: a more important feature of the new form is the occurrence of two sporangia instead of one on each sporangiophore or pedicel.

In the course of his remarks, Graf Solms referred to the unique collection of microscopic preparations of fossil plants left by Prof. Williamson; he emphasised in the strongest terms the immense importance of the collection, and pointed out how every worker in the field of Palæozoic botany must constantly consult the invaluable type specimens in the Williamson cabinets.

On English amber, by Dr. Conwentz (Danzig). The author of this paper gave an account of the Baltic and English amber, and its vegetable contents. After describing the different forms of Tertiary amber, he referred to the occurrence of succinite on the coasts of Essex, Suffolk, and Norfolk; the specimens being usually found with seaweed, thrown up by the tides. Occasionally pieces have been met with weighing over two pounds. Dr. Conwentz described the method of examining the plant fragments enclosed in amber, and compared the manner of preservation with that of recent plant sections mounted in Canada balsam. The amber was originally poured out from the roots,

stems, and branches of injured or broken trees, in the form of resin, which on evaporation became thickened, and finally assumed the form of succinite or some similar substance. For the most part the fossil resin has been derived from the stems and roots of coniferous trees of the genus *Pinus*. In addition to the exceptionally well-preserved tissues of coniferous trees, the Baltic amber has yielded remarkable specimens of monocotyledonous and dicotyledonous flowers. Some of the most striking examples were illustrated by means of the excellent coloured plates from Dr. Conwentz' monographs on the Baltic amber.

The Wealden flora of England, by A. C. Seward. Mr. A. C. Seward, after referring to the various species described by Mantell, Carruthers, Starkie Gardner, and others, from the Wealden strata of England, briefly described a large number of plants from the British Museum collection. During the last few years Mr. Rufford, of Hastings, has obtained an extremely valuable and rich collection of plants from Ecclesbourne, Fairlight, and other localities; and these have now become the property of the nation. The following species are at present known from the Wealden of England; some of these have already been figured in the first volume of the catalogue of the Wealden flora, and the remainder are dealt with in the forthcoming second volume: *Algites valdensis*, sp. nov., *A. catenelloides*, sp. nov., *Chara Knowltoni*, sp. nov., *Marchantites Zeilleri*, sp. nov., *Equisetites Lyelli*, Mant., *E. Burchardti*, Dunk., *E. Yokoyamae*, sp. nov., *Onychiopsis Mantelli* (Brong.), *O. elongata* (Geyl.), *Acrostichopteris Ruffordi*, sp. nov., *Matonidium Goepperti* (Ett.), *Protopteris Witteana*, Schenk., *Ruffordia Goepperti* (Dunk.), *Cladophlebis longipennis*, sp. nov., *C. SCIENCE IN THE MAGAZINES.

THE personal reminiscences of Huxley, contributed by Mr. George W. Smalley to the current number of *Scribner*, will bring up pleasant memories to those who were honoured by the friendship of the departed naturalist, and they form an affectionate tribute "to the memory of one of the truest men who ever lived, one of the manliest, and in all points the noblest." There is in the article so much real testimony to Huxley's greatness, that every student of science will appreciate it. "The emancipation of thought," truly says Mr. Smalley, "that is Huxley's legacy to his century—that was his continual lesson of intellectual honesty." Against those who criticised Huxley's philosophical learning we quote these words: "In truth he was a very expert metaphysician, with an extraordinary knowledge of the literature of metaphysics and philosophy. . . . Huxley was a student, and more than a student, of Descartes. He has written the best short book in existence on Hume. He was a pupil of Aristotle, and therefore not a Platonist. Hobbes taught him much; Berkeley was to him a great thinker; Locke, Butler, and the short list of really great names in English philosophy were all his familiars, while among the great Germans there was, I think, none whom he did not know well—Kant, Hegel, Fichte, and all that illustrious line, not excepting Schopenhauer." But Huxley's claims to recognition as one of the world's foremost thinkers, too unhappily lost to us, need not be enlarged upon here. "He will be remembered as the great physiologist, the great student, the great controversialist, the great thinker and writer. That he will be remembered need not be doubted. The world, it may still be said, does not willingly let die the memory of those who have made it a better world to live in, whose lives as well as whose teachings have been lessons of devotion, of high aims, of wide accomplishments, of honourable purpose; whose achievements are written imperishably in the annals of their own time. Huxley was one of these, and his monument in his life's endeavour. There will be no need to inscribe Right Honourable upon his tomb. The name he bore through life will serve both for epitaph and eulogy."

There are other articles in *Scribner* which will interest the readers of NATURE. One of these is a fully illustrated description of the new Chicago University, by Mr. Herrick. Magnificent buildings have been erected, and an endowment of over £1,200,000 has been bestowed in the short period of four years, as well as a generous annual budget for current expenses. This phenomenal generosity, together with the fact that there will be no question of adequate support as fresh opportunities for development occur, point to the University of Chicago as a great and growing centre of intellectual activity. In some respects the system of the University resembles that of our older Universities, but others—such as the emphasis placed upon the doctor's degree, investigation, research, &c., and the activity of the graduate schools—point to the German University as the prevailing influence. It will astonish many of our schoolmen to know that "the graduates in residence this year—in all over three hundred—form more than one-third of the entire body of students, a larger number than at any other American University. This preponderance of graduate students has been brought about by several reasons: the emphasis placed upon the advanced courses under the leadership of such heads of departments as Profs. Dewey, Hale, von Holst, Laughlin, Michelson and Nef, not to mention others; the special privileges and distinctions granted to graduates (for example, in many departments only graduate students are allowed in the special departmental laboratories, the £6000 annually offered in fellowships and scholarships; and the equal privileges accorded to women. It is a truism that the most distinctive move in American college life of the last decade has been in the sudden interest in post-graduate study. But hitherto in Western institutions, whether college or so-called university, has had the means to provide liberally for advanced studies." It will be clear from this quotation, and more clear from a perusal of the article, that the University of Chicago is developing in the right directions towards scholarship and new knowledge. Chicago people seem to have the cause of higher education at heart, and they are devoting their best energies, as well as generous financial support, to the magnificent institution which has so quickly sprung into existence, and which has such a great future before it.

The third article of scientific interest in *Scribner* is on "Domesticated Birds," by Prof. N. S. Shaler, and is beautifully illustrated.

The sixth of Mr. Herbert Spencer's papers on professional institutions, contributed to the *Contemporary*, deals with the evolution of men of science and philosophers, and will, therefore, be of exceptional interest to our readers. So far as the series has as yet gone, it has been shown that the institutions dealt with were probably derived from the priesthood. Whatever may be the opinion with regard to the connection between the medical profession and priestcraft, it will be generally conceded that astronomy received its first impulse from the exigencies of religious worship. Extracts given by Mr. Spencer from Rawlinson, Layard, and Maury show clearly how closely religion and science (especially astronomical science) were mingled by the Babylonians. With the Egyptians, too, there is abundant evidence to prove an intimate connection between their science and their religion; and the connection is established by the fact that "in every temple there was . . . an astronomer who had to observe the heavens." Astronomy was thus an outgrowth of religion, and the natural knowledge accumulated by the priests formed the beginnings of sciences in Egypt, Assyria, and India. The Greeks imported this knowledge; in other words, they obtained their early science in a slightly developed state. Of the indebtedness of the Greek philosophers to the Egyptian priests there is no doubt whatever, and Mr. Spencer clearly makes out that obligation. The development of Greek science, however, is only in a small measure ascribed to the priesthood, the advances being more of secular than of sacred origin. "During those centuries of darkness which

followed the fall of the Roman Empire," says Mr. Spencer, "nothing to be called science existed. But when, along with gradual reorganisation, the re-genesis of science began, it began as in earlier instances among the cultured men—the priesthood." The man of science and the philosopher have gradually differentiated from the clerical class, one to deal with the concrete and the other to be concerned with abstract matters, and now the distinction between the two is tolerably definite. Simultaneously a subdivision of the body of scientific men has gone on, until we reach these days of minute specialisation. And finally, we have the combination of the units in such institutions as the Royal Society and British Association, and in the serial scientific publications which are general in their scope. In addition to the admirable article summarised in the foregoing, Mr. Spencer contributes to the *Contemporary* a brief note in reply to Prof. Weismann.

A suggestive paper, by Dr. A. R. Wallace, on "The Expressiveness of Speech," appears in the *Fortnightly*. The paper contains a number of interesting facts which point to mouth-gesture as a factor in the origin of language. Here is Dr. Wallace's idea: "In our own language, and probably in all others, a considerable number of the most familiar words are so constructed as to proclaim their meaning more or less distinctly, sometimes by means of imitative sounds, but also, in a large number of cases, by the shape or the movements of the various parts of the mouth used in pronouncing them, and by peculiarities in breathing or in vocalisation, which may express a meaning quite independent of mere sound-imitation." Anthropologists and philologists should be interested in the many facts which Dr. Wallace has brought together in support of his view.

Limits of space prevent us from giving more than brief descriptions of the remaining articles of scientific interest in the magazines received. In *Science Progress*, Mr. F. H. Neville traces recent progress in the study of alloys; galvanotropism in tadpoles is described by Dr. A. Waller, F.R.S.; the chromatophores of animals, by Mr. W. Garstang; the space relation of animals, by Dr. A. Eiloart; and the synthesis of proteids, by Prof. W. D. Halliburton, F.R.S. *Chambers's Journal* has short popular papers on "Horseless Carriages," "New Methods of Illumination," and "Cotton-Seed Oil." In *Good Words* we notice an article on "Falconry," by Mr. R. B. Lodge, illustrated by two photographs from life—one showing a peregrine and partridge, and the other a goshawk and rabbit. The two plates are finely engraved, but we think their value would have been greater had they been photographic reproductions from the original negatives. The *Humanitarian* is distinguished by a psychical article entitled "Dynamic Thought," by Prof. W. F. Barrett; and the *National Review* has a paper in which Selbornians will find pleasure, by the Hon. Mrs. R. Boyle. In addition to the magazines named in the foregoing, we have received the *Sunday Magazine* and *Longman's*.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Five candidates, namely, R. A. Berry, G. Joyce, H. C. Sheringham, W. M. Tod, and B. N. Wale, have been successful in the recent examination in the science and art of agriculture, and have received the University diploma.

Mr. Charles Smith, Master of Sidney Sussex College, and author of several much-used mathematical text-books, was on October 1 admitted to the office of Vice-Chancellor for the current academical year. The outgoing Vice-Chancellor, Mr. A. Austen Leigh, in his parting address to the Senate, referred in sympathetic terms to the loss sustained by the University in the death of Prof. Cayley and of Prof. Babington. He announced that the latter had bequeathed to the University his large and valuable collection of plants. A part of the address was devoted to a description of the difficulties, chiefly financial, which have attended the inception of the Sedgwick Memorial Museum of Geology. The satisfactory progress made with the extension of the Cavendish Laboratory, now approaching completion, was made a matter of congratulation.

Two scholarships in Natural Science, one of £70 and one of £40 a year, will be competed for at Sidney Sussex College on December 12 to 14. Candidates are to make preliminary application to the tutor, Mr. G. M. Edwards.

The late Prof. Babington has left to the University his botanical library as well as his valuable collection of plants.

Mr. H. F. Baker, of St. John's, and Mr. J. E. Edwards, of Sydney, have been appointed the Moderators, and Mr. R. A. Herman, of Trinity, and Mr. H. W. Richmond, of King's, the Examiners for the Mathematical Tripos of 1896.

Dr. Glaisher has been appointed an Elector to the Isaac Newton Studentship in Astronomy.

A complete series of lectures for agricultural students, under the Cambridge and Counties Agricultural Education Scheme, has been arranged for three terms of the academical year. The syllabus is published in the *University Reporter* of October 8.

The first Entrance Scholarship in Natural Science, of the value of £150, into St. Thomas's Hospital Medical School has been awarded to Mr. Frank B. Skerrett; the second, of the value of £60, being divided between Messrs. Walter B. Fry, George W. Hare, and Alfred B. Lindsey, bracketed equal. The Entrance Scholarship, value £50, for students from the Universities, has been awarded to Mr. Percy W. G. Sargent, St. John's College, Cambridge.

At Guy's Hospital, the Entrance Scholarship in Science, of the value of £150, has been awarded to Mr. P. W. L. Camps, and the Second Entrance Scholarship in Science, of the value of £60, has been awarded to Mr. S. Hodgson.

The Treasury has decided that the annual grant of which King's College, London, was deprived under the late Government may be restored to the college next year without any stipulation as regards tests.

SCIENTIFIC SERIALS.

American Meteorological Journal, September.—Synchronous or simultaneous geographical distribution of hourly wind velocities in the United States, by Dr. F. Waldo. This article is part of a memoir prepared for the U.S. Weather Bureau, and is supplementary to one which appeared in the *Journal* for July (Nature, p. 335). Charts are drawn for midnight and noon, for the extreme months of January and July, for about the centre of the United States, and afford a comprehensive view of the synchronous wind conditions and relations as regards the average velocities. This method of representation obviates the necessity of a lengthy text.—The origin and work of marine meteorology, by Lieut. W. H. Beehler, U.S.N. The author deals more particularly with the history and development of this service in the United States, from the appointment of Lieut. Maury as Superintendent of the U.S. Naval Observatory, in 1844, which led to the Maritime Conference held at Brussels in 1853. The numerous charts published by the American Office formed the basis of the useful wind charts subsequently issued by the Meteorological Department of the Board of Trade, during Admiral FitzRoy's lifetime, and which were widely distributed among seamen. The U.S. Hydrographic Office was established in 1866, and in 1893 there were nearly 3000 observers co-operating with it. The outcome of this was the publication of the Pilot Chart of the North Atlantic Ocean, to which we have often had occasion to refer. About 4000 copies of this chart are distributed monthly, and among other things they have done much towards bringing about the general recognition of the value of the use of oil to still the waves, by which numbers of vessels have been saved from total loss.

Bulletin of the American Mathematical Society (vol. i. No. 10, July 1895).—This closing number of vol. i. contains, in addition to the usual list of new publications and the index, a list of the published papers read before the Society during the year, together with the places of their publication.—Mr. J. M. Brooks gives a clear account of Lie's work on continuous groups *à propos* of Scheffers' edition of the Vorlesungen uber Continuirliche Gruppen mit geometrischen und anderen Anwendungen. "The importance of the group idea itself has long been recognised in its application to the theory of substitutions, and some continuous transformations, such as the pedal transformation, were in use before Lie's work, but were used without their connection with the group idea being discovered, and the discovery and the presentation of the results of it in a systematic form are due to Prof. Lie." Dr. Scheffers has aimed at giving in outline the general theory, and he indicates some lines in which it may be applied.—Prof. J. Harkness, in a review of the second volume

second edition) of Jordan's "Cours d'Analyse de l'ecole Polytechnique," which is devoted to the integral calculus, fully analyses its contents, and pronounces it to be "a substantially new contribution to mathematical literature." "From beginning to end the reader feels that he is being guided by a master-hand."—Prof. F. Hastings Moore writes on a theorem concerning reduced characteristics with denominator 2 (of Prym's "Untersuchungen über die Riemann'sche Thetaformel und die Riemann'sche Charakteristikentheorie," 1882).—A note on the Transitive Substitution Groups of degree 12, by Dr. G. A. Miller, mentions that Camille Jordan in the *Comptes rendus* (vol. lxxv. p. 1757) states that there are *three* primitive groups of degree 12, excluding the groups which contain the alternating group. Dr. Miller has found *four* multiply transitive primitive groups of this degree, excluding the two groups containing the alternating group. The proof is given in the present note.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 30.—M. A. Cornu in the chair.—The Perpetual Secretary read a letter from M. J. B. Pasteur, announcing the death of his father, Louis Pasteur, who died at Villeneuve-l'Etang (Garches), on September 28, 1895. M. A. Cornu then expressed the deep feeling of loss in the Academy, and recalled the greatness of the work accomplished by Pasteur. As a mark of respect and sorrow the Academy adjourned after receiving the correspondence. Remarks on the subject of Lord Salisbury's discourse "on the real limits of our science," by M. Emile Blanchard. The author recalls his work in contradiction to the theory of the origin of species advanced by Darwin, and maintains that no single instance has ever been brought forward in answer to his challenge which can be held to verify the assumption that one species may be produced from another by any form of selection.—On glycosuria following ablation of the pancreas, by M. R. Lépine. The sugar contents of the urine have been determined, and glycosuria traced during the first thirty hours, operating on dogs without the use of anæsthetics or morphine.—A study of the mechanical theory of heat, by M. Ch. Brun, has been printed in the correspondence.—The evaporation of liquids and the great capillary theories, by M. G. Van der Mensbrugghe. Most liquids evaporate spontaneously in the air. The consequences follow: (1) The liquid layer whence particles are continually being detached to form vapour cannot have the same density as the liquid in the interior of the mass, otherwise there would be an abrupt passage from the liquid state to vapour; it must, therefore, be admitted that the density of the superficial layer decreases towards the exterior. All capillary theories, supposing liquids incompressible (Laplace), or of the same density throughout (Gauss), are therefore inadequate. (2) When the mass considered is very small (bubbles, liquid films), evaporation causes loss of a perceptible fraction of the total weight. Hence capillary theories regarding a liquid mass as having an invariable volume (Poisson) must be condemned. (3) The constant renewal of the free surface of the superficial layer proves, without possible doubt, that this layer is not in equilibrium. What confidence can then be placed in the theories of Laplace, Gauss, and Poisson, and the works of contemporary analysts Neumann, Mathieu, Van der Waals, Resal, and Poincaré, who formally suppose a liquid mass in equilibrium? After calling attention to the defects of former theories, the author quotes his own theory, derived from a consideration of molecular forces, as giving a sufficient explanation of these consequences.—On a new nitrogenous manure, calcium cyanate, by M. Camille Faure. It is asserted that calcium cyanate can be produced in large quantity in the electric furnace by heating lime and charcoal intensely in an atmosphere of nitrogen, and oxidising the product by air. The cyanate contains a greater proportion of assimilable nitrogen than nitrate, and can be used as a manure.—Syntheses by means of cyanacetic esters, by M. T. Klobb.—Constitution of acids produced in the oxidation of inactive campholenic acids, by M. A. Béhal. The acid $C_6H_{10}O_4$ is dissymmetric dimethylsuccinic acid; the acid $C_7H_{12}O_4$ is one of the two dimethylglutaric acids having the two methyls attached to the same carbon atom, probably $CO_2H.C(CH_3)_2.CH_2.CH_2.CO_2H$. The author claims priority for his work against that of Tiemann.—On the effects of the synodic and anomalistic revolutions of the moon on the distribution of pressure in spring, by M. A. Poincaré.—On a double night ascension (balloon) made on September 4, by MM. G. Hermite and Besançon. Two balloons made voyages from Paris in opposite directions, starting at the same time. The currents observed and used are described, together with details of the voyages.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—A Hand-book to the Birds of Great Britain: Dr. R. B. Sharpe, vol. 2 (Allen).—Climbing in the British Isles: W. P. H. Smith and H. C. Hart, II. Wales and Ireland (Longmans).—Practical Proofs of Chemical Laws: V. Cornish (Longmans).—An Introduction to the Study of Seaweeds: G. Murray (Macmillan).—Catalogue of the Library of the Royal Geographical Society: Dr. H. R. Mill (Murray).—Dynamics: Prof. P. G. Tait (Black).—Farm Foods, or the Rational Feeding of Farm Animals: Prof. E. v. Wolff, translated by H. H. Cousins (Gurney).—The Gold Mines of the Rand: F. H. Hatch and J. A. Chalmers (Macmillan).—The Fauna of British India, including Ceylon and Burma; Birds, Vol. 3: W. T. Blanford (Taylor and Francis).—Popular History of Animals for Young People: H. Scherren (Cassell).—Moral Pathology: Dr. A. E. Giles (Sonnenschein).—The Splash of a Drop: Prof. A. M. Worthington (S.P.C.K.).—Simple Methods for detecting Food Adulteration: J. A. Bower (S.P.C.K.).—Biology Notes, Vol. 1 (Chelmsford).—Einführung in das Studium der Bakteriologie: Dr. C. Günther, Vierte Auflage (Leipzig, Thieme).—Natural History of Selborne: Gilbert White, 2 Vols. illustrated (Macmillan).—The Scientific Foundations of Analytical Chemistry: Prof. W. Ostwald, translated by Dr. G. M'Gowan (Macmillan).—The Structure of Man: Dr. R. Wiedersheim, translated by H. and M. Bernard (Macmillan).—Weather and Disease: A. B. MacDowall (Graphotone Company).—Old Farm Fairies: H. C. McCook (Hodder and Stoughton).

Pamphlets.—Les Limites Actuelles de Notre Science: Marquis de Salisbury, translated by W. de Fonvielle (Paris, Gauthier-Villars).—Reaction!: K. Pearson (Reeves).—Guide to the Collections of Rocks and Fossils belonging to the Geological Survey of Ireland: A. McHenry and W. W. Watts (Dublin, Thom).—A Supplement to a Revised Account of the Experiments made with the Bashforth Chronograph: F. Bashforth (Cambridge University Press).—Ein Brauner Tschimpanse im Dresdner Zoologischen Garten: A. B. Meyer (Berlin, Friedlander).

Serials.—Journal of the Royal Agricultural Society of England, Vol. vi. Part 3 (Murray).—Natural History of Plants: Kerner and Oliver, Part 16 (Blackie).—Mind, October (Williams and Norgate).—Transactions of the Perthshire Society of Natural Science, Vol. 2, Part 2 (Perth).—Geological Magazine, October (Dulau).—Morphologisches Jahrbuch, 23 Band, 1 Heft (Leipzig, Engelmann).—Bulletin de la Société Impériale des Naturalistes de Moscou, 1895, No. 2 (Moscou).—Geographical Magazine, October (Stanford).—Story of the Heavens: Sir R. S. Ball, Part 1 (Cassell).—Ethnologisches Notizblatt, Heft 2 (Berlin, Haack).—Bulletin de l'Académie Royale des Sciences de Belgique, 65^e Année, No. 8 (Bruxelles).—American Naturalist, October (Philadelphia).—Annals of Scottish Natural History, October (Edinburgh, Douglas).—Memoirs and Proceedings of the Manchester Literary and Philosophical Society, Vol. 9, No. 6 (Manchester).—Science Progress, October (Scientific Press).—Illustrated Archæologist, and Reliquary, October (Bemrose).—Travaux de la Société des Naturalistes de St. Pétersbourg, Vol. xxiii. (St. Pétersbourg).

CONTENTS.

THURSDAY, OCTOBER 17, 1895.

RECENT ORNITHOLOGY.

The Land Birds in and around St. Andrews. By George Bruce. Dundee: John Leng, 1895.

The Migration of British Birds, including their Post-Glacial Emigration, as Traced by the Application of a New Law of Dispersal. By Charles Dixon. (London: Chapman and Hall, 1895.)

Heligoland as an Ornithological Observatory, the Result of Fifty Years' Experience. By Heinrich Gatke. Translated by Rudolph Rosenstock, M.A. Oxon. (Edinburgh: David Douglas, 1895.)

A Hand-book to the Game Birds. By W. R. Ogilvie-Grant. Vol. i. Sand-grouse, Partridges, Pheasants. (London: Allen and Co., 1895.)

The Land-birds and Game-birds of New England, with Descriptions of the Birds, their Nests and Eggs, their Habits and Notes. By H. D. Minot. With illustrations. Second edition. Edited by William Brewster. (New York: Houghton and Co., 1895.)

Wild England of To-day, and the Wild Life in it. By C. J. Cornish. (London: Seeley and Co., 1895.)

The Pheasant: Natural History. By the Rev. H. A. Macpherson. *Shooting.* By A. J. Stuart-Wortley. *Cooking.* By Alexander Innes Shand. (*The Fur and Feather Series.* London: Longmans, Green, and Co., 1895.)

NO section of vertebrate zoology has in this country attracted more amateur disciples than ornithology; and the literature of perhaps no other group has been burdened by so many useless contributions by writers who, possessing not only little literary qualification for the task, but a very superficial knowledge of the subject, rush into print, assuming that, because they are able to see, they are capable of observing, which are two very different things. Among the number of such contributions must be included a volume of 563 closely-printed octavo pages on "The Land Birds about St. Andrews," by Mr. George Bruce. On the book opening of its own accord at p. 44, the heading of "The Griffon Vulture" caught the eye and surprised us not a little; for the addition of this majestic bird to the avifauna of Fifeshire was quite new to us. On consulting the title-page, however, we discovered that the work was of wider scope than indicated on the cover, and included "a condensed history of the British land birds, with extracts from the poets and observations and anecdotes on natural history." "The single occurrence of a solitary specimen" in Ireland, recorded by Yarrell, is apparently sufficient excuse for this page of padding. A carefully-written account of the birds of Fifeshire would have been welcomed to our lists of local faunas; but with so many excellent histories of British birds in existence (such as that by Mr. Howard Saunders, to mention only one), there was hardly a call, one would have thought, for another, except it were commended by some special feature or novel method of treatment. The special features of this book appear to consist in the superabundant extracts from the poets—more or less, generally less, *à propos*—cuttings from the local newspapers, and quotations from many other sources equally authoritative. Although the "history," such as it is, is very condensed, and not always to be taken on trust, and the anecdotes poor and pointless, there are, nevertheless, in the book not a few observations which we are confident will prove new to most ornithologists. Of these we cull a few, and refer our readers, who desire to dig deeper, to the book itself for others.

"The Isle of Man has proved one of the best stations in Scotland for migration observations."

"The species means every individual bird in creation: for instance, a lark is one species. . . . A genus is a group of these birds so closely resembling each other as hardly to be mistaken, as the raven, the carrion crow. . . . These combined form the genus called *Corvus*, which means in British [*sic*] crow. The plural of *Corvus* is *Corvine*, as genera is the plural of genus."

"Among those naturalists who have recently [!] done so much for the advancement of this branch of science Temnick [!] and Montague [!] deserve to be ranked amongst the first."

Mr. Bruce records the occurrence of the nightingale as far north in Scotland as Paisley and Uddingston, upon the unquestioned authority of one James Anderson in a letter to a local newspaper, apparently. The *Struthionidæ*, we find here, are represented in the British Isles by the genus *Otis*, and that the author of the species *Ulula stridula*, *Salicaria arundinacea*, and *S. phragmites* is Mr. George Bruce, of St. Andrews! According to the title-page he is also the author of "Destiny and other Poems," of which we must confess our ignorance. We trust, however, that the doom of "The Land Birds of St. Andrews" may have no prejudicial effect on his earlier volume.

"The Migration of British Birds" is the new work by Mr. Charles Dixon, which was heralded a short time ago by an article in the *Fortnightly Review* from his own pen. This author's previous volume on a similar subject was exhaustively discussed in NATURE for December 1892. On that occasion the deliberate conclusion was expressed "that Mr. Dixon, author of so many works as he may be, is no authority on the subject of migration, which he has left exactly as he found it." The same verdict must be passed on the present volume, and we might have dismissed it without further discussion but for two reasons. The first is the fact that in one or two important daily journals, whose scientific reviews in general command our entire respect, Mr. Dixon has been rather prematurely elevated to the rank of a Moses in ornithology, and the other is that he declares that his present views are now opposed to those he has expressed in previous works. Whether the abandonment by Mr. Dixon of his former views is due to the criticism to which they were subjected in NATURE, we have not the satisfaction of being informed.

This "new Law" here promulgated to the world (not yet accepted by it) is the "undiscovered principle" which is to solve all the difficulties of geographical distribution, and the dispersal of life, and clear up "the greatest mystery which the whole animal kingdom presents," to quote the words of one of our foremost ornithologists—"a mystery which attracted the earliest writers, and can in its chief point be no more explained by the

modern man of science than by the simple-minded savage or the poet or prophet of antiquity." When writing these pregnant words it was not given to this erudite biologist to foresee the revelation of "this Our new law" of dispersal to Charles Dixon, of which the volume under notice is the first proclamation. This great new "law forbids retreat." To Mr. Dixon it has been revealed that the effect of the slow oncoming of a glacial epoch in either hemisphere was not to cause bird-life to retreat in front of the increasing cold, but really to exterminate all those birds having a range of distribution entirely within the refrigerated areas, and to contract the range of such as were migratory. Those birds alone survived, therefore, whose former range extended beyond the glaciated areas (the unglaciated portions of their range the author calls "refuge areas"); while all those birds which had no refuge area were totally exterminated, and have since been lost to science. The "law," moreover, forbids species in the northern hemisphere ever to increase their range in a southerly direction, and species in the southern hemisphere ever to increase theirs in a northerly direction; and only those northern birds or those southern birds whose refuge areas extended on both sides of the equator are permitted by the "law" to extend their breeding range to regions towards the opposite pole, which presented the most favourable conditions for reproduction. Now "this Our law," we are told, applies not only to birds, but to all life, and is a universal explanation never thought of by any other "biologist of note," of the migration and geographical distribution of species. To show that this is so, Mr. Dixon applies his law to the distribution of "arctic" types in the flora of the southern hemisphere. Sir Joseph Hooker long ago explained the presence of the "Scandinavian" element in that flora, by indicating its migration routes along the meridional highlands of the great continental land masses. Hooker, Huxley and Wallace, and doubtless all those other ornithologists and geologists—among whom are Sharpe and Geikie—who have, according to Mr. Dixon, gone "beyond their last," have been quite misguided by reason of their ignorance of this law. Our latest authority, however, declares with all the emphasis of certainty that "there can have been no emigration of plants from north to south"; "it could never have taken place"; Our "law forbids it." The true solution of the question by Mr. Dixon is, that all the "arctic" plants in the southern as well as in the northern hemisphere, spread from an equatorial centre. Let us take, for example, an "arctic" species common, say, to high northern latitudes, and to New Zealand, and the Southern Andes or South Africa. This species must, in the first instance, have arisen in some part of the equatorial regions from a tropical form, by ascending to the cool arctic zones of one of the mountains—suppose in South America. It must then have followed one of two routes of dispersal. After multiplying it must either have spread right round the equator (the absence of continuous land notwithstanding), crossing again and again the torrid interspaces separating it from other equatorial altitudes, which served it as stepping-stones, till it attained those longitudes whence it could extend its range, as best it might, to its [illegible] northern and southern habitats—a migration-route too remarkable to be easily credited. The alternative route, so far as regards the southern hemisphere, at all events, would be for the species to spread southwards on one of the continents (say South America), till reaching a then-existing Antarctic land, over which it must have gradually dispersed, and in order to reach South Africa or New Zealand, it would have to travel northwards in the very face of Mr. Dixon's inexorable law, which it would thus entirely upset, and with it all the conclusions in the present treatise. How would Mr. Dixon explain, for instance, the distribution of *Petraea arborea* in South America, in West Java, and East Timor? Another method of dispersal may perhaps be predicated as possible by some, namely, the *independent* origin from equatorial ancestors of identical arctic species in high northern and southern latitudes; but any such occurrence is too improbable to be seriously entertained.

This law, which seems to us to fail most lamentably to explain the dispersal of plants, fails not less in regard to the migration of birds. It surely requires no pointing out that during every winter we have numberless boreal species (birds, whales, seals) visiting our shores in retreat south into more genial climes; the sheep feeding on any high hill, and overtaken at the beginning of winter by storms, hasten for food and shelter to lower levels, where they would continue to remain if there came no moderation in the weather of the uplands; and our resident redbreasts for the same reason retreat from the woods before the first snows to the neighbourhood of our homes, and if the winter be specially severe they retreat still further in search of more genial conditions—they do *not* dare the storm and die on the snow. What takes place in miniature during the winter would simply be enacted, there is little doubt, on an extensive scale during a glacial epoch. The migration, to be seen to-day in Western Europe, we are told by Mr. Dixon, was undoubtedly initiated with the passing away of the third glacial period, is undertaken expressly for purposes of reproduction, and is "the constant endeavour of what we must now regard as but the relics of such exiled life to regain and repeople the area that it once occupied during pre-glacial time." Had the migration of pre-glacial times a different cause or motive than that of to-day? Why is migration necessary for the purposes of breeding? Is there not space enough, food enough, and a better climate in the regions where the migrants winter, and to which the parents, indeed, return reinforced by their young, to be dependent on the supplies of that area? How, we may also ask, can the birds which occupied the southern and non-glaciated portion of their range be inspired by "a constant endeavour to regain" an area their parents had never occupied, and had never even known; for those of their species which had occupied and known the northern part of the range, we are assured rather than retreat a step, chose to die under Dixon's "law." The new Commandment which forbids a southern extension of breeding area, "renders," according to Mr. Dixon, "a flight south in spring impossible"; and "all species do not breed [more grammatically, no species breeds] anywhere south of their [its] point of entrance." Yet the penguins defy this law, and though southern hemisphere birds, they migrate equator-wards to breed. In the spring of this year the present writer witnessed, in

the middle of the Irish Sea, a flock of migratory birds crossing (the weather having been specially fine for some time) to England, from Ireland apparently, on a *south-east* course. Before crediting this lob-sided partially-radiating dispersal, we must have more convincing proofs that birds and plants are so peculiarly constituted that an invisible parallel of latitude athwart a congenial region, is, in a particular compass bearing, as impassable to them as an ocean or a sahara. We cannot affect to believe that Mr. Dixon's is a more satisfactory explanation of the mysterious season-flight of birds, than the cause (among others) long ago assigned, that the migrant species come north in spring to breed, impelled by a hereditary impulse at that season (and probably guided by a direction-sense with which they are specially endowed), to return to their old nurseries from the regions whence their ancestors were compelled by geologic and climatic causes to retreat, and in which they were so long acclimatised as to be now unable to withstand the cold winter, with its meagre fare, of their ancestral *patria*, which consequently they forsake again in the autumn.

We cannot afford space to touch on many other points in Mr. Dixon's book in which we believe he has gone astray. We feel no nearer a solution of the mystery of migration than before its publication. Writers on this subject "should thoroughly understand not only the rudiments of the higher philosophy [whatever that may mean] of the geographical distribution of life before they attempt to theorise upon it, or endeavour to demonstrate it." We offer Mr. Dixon his own advice, which we have copied from a paragraph in which a charge of *ultra crepidam* is ill-naturedly levelled at some of the foremost workers in the science with which he is dealing, and to which their lifetime has been unremittingly devoted—a charge which surely comes ill from one who is purely an amateur, and a young man compared with the veterans at whom he sneers.

Mr. Dixon's style is cumbrous and not always easy to comprehend, while his English is often very ungrammatical. It is only justice to admit that the book, with the *theories* of which we so entirely disagree, contains much interesting information collated and condensed from many sources.

It is refreshing to turn from these airy speculations to the stable ground of pure and unadulterated fact with which the pages of "Heligoland as an Ornithological Observatory" are so lavishly filled. This is the English translation by Mr. Rosenstock of Herr Gätke's celebrated volume published in German in 1890. Ornithological students in England owe their heartiest thanks to the translator, as well as to Mr. Harvie Brown, to the publishers, and to all who have given a forwarding hand to the task of presenting them with this great and important work in their own language. The labours of its venerable and distinguished author are too well known in this country to require us to do more than recommend his book—corrected by the author down to May last—in its new garb. Binding, printing, paper, and illustrations are all that can be desired. In turning over its pages we recognise anew the trustworthy observer, and are reminded of the story told of an old woman in a northern county of Scotland, who, on being taken to task by her minister for invariably paying the closest attention to any stranger who occupied the pulpit, and of as persistently sleeping in unbroken repose throughout his own sermons, replied, "Hoot minister! wha's to ken fat kin' o' doctrine they youngsters may be gi'in'; we a' ken fine that we can lippen to yoursel'." Herr Gatke's book can be perfectly "lippen"-ed to. It is divided into three parts, the first of which—on the migration of birds—is perhaps the most important and interesting. This subject is discussed in nine chapters, dealing with the course of migration in Heligoland; the direction, altitude and velocity of the migration flight; the meteorological conditions influencing it; the order of migration; exceptional phenomena; what guides the birds, and the cause of the movement. In regard to the last, we quote the conviction of this patient observer and recorder after fifty years' experience, "that what at present has been ascertained in reference to the migration of birds furnishes us with no clue, by the aid of which we are enabled to penetrate the depths of this wondrous mystery." The second part deals with changes which he has observed to occur in the colour of the plumage of birds without moulting. This subject has also been studied by Mr. Ogilvie-Grant, of the British Museum, who has not only corroborated the truth of Herr Gatke's observations, but thrown much new light on the subject. The final section of the book gives an account of the birds observed in Heligoland, which number 398. The volume is illustrated by a number of charming vignettes, and by two excellent portraits of Herr Gätke.

The latest addition to the naturalist's library, edited by Dr. R. B. Sharpe, and published by Messrs. Allen and Co., of Waterloo Place, is a "Hand-book to the Game-birds," by Mr. W. R. Ogilvie-Grant, who is well known to be an authority on this group. This is the first of two volumes, and contains an account of the sand-grouse, partridges and pheasants. The second volume (which will be issued shortly) will deal with the American partridges, the megapodes, curassows and hemipodes. The hand-book is founded on the author's British Museum catalogue of the group (vol. xxii.), and is one of the best yet issued of the valuable series to which it belongs. So far as published, the volumes of Allen's Naturalist's Library are each of them concise monographs of the groups they relate to, well illustrated and published at a very low price. The aim of the author has been to treat the subject in such a way that it may not only be useful as a scientific work of reference, but also as a handy book for sportsmen and field naturalists. With its aid they should be able not only to identify the birds they shoot with as little trouble as possible, but also to find out what is known concerning the life-history of each species. The work will be specially valuable to the museum curator; indeed, it is the only handy and up-to-date monograph of the families it describes. This volume contains twenty-one full-page coloured illustrations, some of which are republished from Jardine's Naturalist's Library; the majority, however, have been specially drawn for it by Mr. Keulemans. It is to be regretted that Messrs. Allen do not see it to their advantage to dispense with the

antiquated figures of the former edition, for when they are placed beside Mr. Keulemans' beautiful plates, the contrast is too striking not to call forth unfavourable remark. The birds from the hand of that artist seem transported fresh from the heaths and the hills; the others look like worn museum specimens. A special feature in Mr. Ogilvie-Grant's hand-book, is the full account given of the various phases of the moult in the grouse, partridge and blackcock, and of the curious change of plumage that takes place in these birds without moulting. We are indeed indebted, as observed above, to him more, we believe, than to any other, for the elucidation of these interesting, and to a great extent inexplicable, variations. The account he gives of the plumage-changes in the blackcock (*Lyrurus tetrix*) have never till now been so fully described. We understand that the description of both male and female of every species has been carefully made from the actual skins, and checked with the specimens, in proof. This is sufficient to establish the accuracy and value of Mr. Ogilvie-Grant's work. The only doubtful statement we have detected is on p. 189, where the author has stated, following the authority of Sir Walter Buller, that the New Zealand quail, now extinct in that colony, still exists on the Kermadec Islands. We are inclined to believe that its discovery on the latter island was a mistake, and that this interesting bird is now absolutely exterminated.

"The Land-birds and Game-birds of New England" is a new edition of this local fauna published some nineteen years ago. Its author is the late Mr. Henry D. Minot, who, as we learn from a biographical notice which prefaces the book, had from early childhood showed a great fondness for nature, and who, devoting himself to the study of birds, had completed the manuscript of this volume of over 400 closely-printed pages in his seventeenth year. This new edition issues from the press under the care of the distinguished ornithologist, Mr. W. Brewster, who says that the book was well received on its appearance, sold rapidly, and soon became out of print. Mr. Minot adopted the profession of a railroad engineer, and for fifteen years lived in the hope of adding to, and correcting his published observations. His duties, however, prevented him from accomplishing this task, and his career terminated in 1890 by his being killed in a railway collision. Written by a youth of seventeen, as the editor observes, "with, as I am assured, almost no outside help of either a literary or scientific kind, it is a remarkable and interesting book, for most of the [bird] biographies relate to his own experiences or impressions." The book is certainly worth republishing. The original text has been left almost untouched, and a few notes found in Mr. Minot's annotated copy are inserted at the foot of the pages. As could not but happen in one so young, there are not a few errors, both of fact and deduction; but the "editorial touches" of Mr. Brewster have safeguarded the reader against being misled, and given to the book much of the value it now possesses. Mr. Minot was a keen observer, and the [illegible] apart from what it possesses as a local fauna, and from Mr. Brewster's annotations, lies in his [illegible] of the habits of the New England birds. [illegible] much accurate and [illegible], recorded in a pleasant and easy style. In speaking of the quail (*Colinus virginianus*), he racily describes the unsuccessful pursuit of a covey by a young "gunner," and concludes: "Now the lad returns home, and explains his ill-luck by an extraordinary theory, read of in books, and verified by his own experience, that our Quail have a wonderful power of retaining their scent. The only sound argument to prove this statement is that our game-birds, when very young, by a thoughtful provision of nature, emit little or no scent." In later years the author added this note. ". . . When game-birds drop suddenly to the ground and remain motionless, the dog does not perceive them. Quail most frequently alight in this way, but as soon as they begin to move, the effluvium escapes and is disseminated." Mr. Brewster adds his "editorial touch" to the following effect: "The question cannot be settled in this summary manner, for the writer overlooks the important fact that the habit of retaining scent is not common to all the quail of any one locality or region. On the contrary, it is peculiar to certain individual or bevies who invariably practise it when pursued by sportsmen. Yet these individuals do not drop more suddenly, nor remain more motionless, than the less fortunate birds which the dogs easily find and point." Thus author and editor.

The illustrations consist of woodcuts in outline, but though "drawn from nature," are of no practical use, and might have been omitted with advantage. The book is well printed, and has, as frontispiece, a portrait "prepared and engraved by Mr. A. F. Jaccaci as a personal tribute" to the talented but unfortunate author.

In "Wild England of To-Day," by Mr. Cornish, we have a collection of essays republished from different journals, but chiefly from the *Spectator*, describing the life in various "wild," secluded or thinly populated districts of the country "ranging from the southern cliffs to the Yorkshire fen." Although we find such subjects discussed as "salmon-netting at Christchurch," "trout-breeding," and "the deer in Richmond Park," the majority of the papers are devoted to bird-subjects, and thus come lawfully within the scope of this article. The whole of the sketches, while quite popularly written, are scientifically accurate, without being or pretending to be permanent contributions to science. Charmingly indited, they remind one of the style and flavour of the late Richard Jefferies' psalms in praise of nature. The book is adorned by a number of full-page illustrations of exceptional excellence, from photographs and from drawings specially made for it, of which the "Peewit's Nest," by J. W. Oakes, A.R.A., deserves special mention as an exquisite little picture.

The latest addition to the attractively bound "Fur and Feather" series, whose volumes form such pleasant journeying companions, is "The Pheasant." The Rev. H. A. Macpherson treats, as he does in several of its predecessors, of the natural history of the bird. He discusses concisely its acclimatisation from the earliest times, its geographical distribution and its nesting habits, while under the heading of "Freaks and Oddities" he describes its plumage changes and its cross breeding. This section concludes with two chatty chapters on "Old World Fowling" and "Poaching in the Nineteenth Century."

Mr. Stuart-Wortley discourses with authority on how to shoot—slaughter?—this tame "Byrd of singular beauty," when driven in bevies slowly and with not a little persuasion just sufficiently far away to "home," on being flushed, at a proper altitude over the guns, which are thickly stationed in hiding to rain a murderous hail on them. The shooting of the wild-bred bird is, however, nobler sport. "Nothing strikes one more in Norfolk," says Mr. Stuart-Wortley, "especially in the heath district, than the prevalence of pheasants everywhere . . . and it adds greatly to the charm of a partridge drive when it is varied by a few rocketing pheasants out of the belt you are standing by, or when they rise high off the heath and come over with the partridges, and quite as fast. . . . The late October days in Norfolk and Suffolk, especially where there is heath, are among the most fascinating to be got in England."

Mr. Innes-Shand plays on our salivary glands by extolling the excellence of the bird "when she is in the dish," roast and with bread-sauce, and in many a fascinating style besides that "sublimest form of art . . . the *faisan à la Sainte-Alliance*." Altogether "The Pheasant" is, as remarked above, a delightful *compagnon de voyage*, and will be found in many a portmanteau in the late October days. The ten well-produced full-page plates add much to the attractiveness of the volume.

OUR BOOK SHELF.

The Elements of Botany. By Francis Darwin, M.A., M.B., F.R.S., Fellow of Christ's College, Cambridge, and Reader of Botany in the University. (Cambridge: University Press, 1895.)

IN this little book the elements of botany are presented in a more refreshing form than is too often the case. The author has chosen to emphasise certain principles and phenomena of morphological or of physiological importance, rather than to crowd his pages with vast numbers of facts. Various plants are requisitioned to serve as illustrations of the different subjects under treatment; and thus the student will certainly acquire a clearer and more general conception of what, for instance, a flowering plant is, and how it lives, than would have been possible had only one example been selected as a type, even though this had been far more exhaustively dealt with.

There are some matters, however, in which it may be doubted whether the method of treatment adopted will commend itself equally to most botanists. Thus, although Mr. Darwin says that he advisedly puts the doctrine of alternation of generations into the background, many will doubtless regret his decision. It is true that without the introduction of a few more intermediate types, the question would possess, as the author says, but little interest for the elementary student. But in view of the great importance, both of the facts and of the comparisons based upon them, one cannot help wishing that the general bearings of the question could have been indicated somewhat more fully.

A second matter is the employment of the term *bark* in the popular, as opposed to its more technical, sense. Botanists have come to attach a special and restricted meaning to the term; and though it is no doubt highly improper to pirate English words, still this is done in every technical department, and thus, in spite of its admitted inconvenience to the beginner, we think the balance of advantage is in favour of the retention of the appropriated word in its restricted significance.

But these are cases in which there is room for difference of opinion; there will be none at all on the question as to the merits of Mr. Darwin's book considered as a whole. It is an admirable work which both teacher and student will cordially and deservedly welcome.

The Book of British Hawk-Moths, a Popular and Practical Handbook for Lepidopterists. By W. J. Lucas. With illustrations from Nature by the Author. (London: L. Upcott Gill, 1895.)

THERE is a great flood of books on the larger and more showy British *Lepidoptera* issuing from the press at the present time; but so long as the information which they contain is fairly accurate, and they place on record a portion of the floating information derived from periodicals or personal observation, we do not see that the fact is to be regretted. At least it is a sign that an intelligent interest in entomology is now taken by a large number of persons who are not entomologists or collectors themselves; for we do not believe that there is a sufficiently large number of entomologists to buy up the large editions of popular books which are now offered to them: they must appeal to a considerable number of outsiders as well.

The book before us is restricted to a very small group of British moths, the *Sphingidæ* proper, numbering only seventeen species, several of which are possibly only casual visitors rather than permanent residents. Consequently, the author has been able to treat of the subject in considerable detail, though a good deal of the introductory part of the book deals with the collecting and preserving of *Lepidoptera*, rather from a general point of view, than as specially applicable to *Sphingidæ*. The illustrations consist of folding plain plates, representing the larva, pupa, and imago of each species, the earlier stages, when not observed by the author himself, being usually copied from Buckler's work on larvæ. There are also occasional woodcuts in the text. The letterpress is pleasantly, though sometimes hastily, written, and is fairly complete and up to date; and most of the illustrations are good. On the last plate, the names of the two bee hawk-moths appear to have been reversed, probably by a printer's error. The information given is, we believe, accurate; but every entomologist will be able to supplement it according to his own experience. Thus, it might have been stated that *Smerinthus tiliæ* (the lime hawk-moth) is one of the commonest of the *Sphingidæ* in the suburbs of London. *Sphinx pinastri* (the pine hawk-moth) is mentioned as sometimes found at rest on the trunks of pine trees. So it is; but it will also rest on other trees, and on the continent it is often found resting on the trunks of the poplars which often fringe the roads in the neighbourhood of pine forests.

W. F. K.

Biology Notes. Vol. i. Edited by David Houston, F.L.S. Pp. 290. (Chelmsford: Technical Laboratories, 1895.)

THIS volume is a collection of bulletins published monthly by the Technical Instruction Committee of the Essex County Council, as an aid to the teaching of biology. It contains information bearing upon the applications of biology to the industrial pursuits of the county, and notes of interest to biological students. Among the subjects of short articles are ergot and its physiological effects, bracken poisoning of cattle, biological aspects of dairying, injurious insects, diseases of cultivated plants, zoology on the Essex coast, and spraying experiments; and there are also included in the volume several detailed syllabuses of courses of practical instruction in vegetable and animal biology. The "Notes" are well illustrated, and must be of great assistance to the students in the classes controlled by the Essex County Council. Other County Councils would do well to issue monthly bulletins of the kind collected in this volume.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The University of London.

I HAVE been away from home, and have only now seen Mr. Thiselton-Dyer's letter of August 23.

My previous letters were, I thought, quite clear: but as he asks me to do so, I write to explain that my two statements which he quotes, viz.: (1) "I am not asking that any privilege which they do not at present possess should be conferred upon my constituents, but only supporting what is now their legal right. . . . This right I know they highly value"; and (2) "It is the law at present," had reference to the present right of veto possessed by Convocation.

As regards the vote being taken as at a senatorial election, so far from stating that this was at present the law, the very terms of my letter implied that it was a change.

Whether it would be "radical" or "revolutionary" is, of course, a matter of opinion, but I certainly did not make the suggestion with the object attributed to me; nor do I share my friend's opinion that the graduates would take a course which, to quote his words, "would destroy the prospects of Academic study in London." JOHN LUBBOCK.

High Elms, October 8.

Sir Robert Ball, and "The Cause of an Ice Age."

MR. JAMES GEIKIE has recently brought out another edition of his "Ice Age," a well-known and influential work. In this book he quotes freely from Sir Robert Ball's "The Cause of an Ice Age," which appeared in 1891, and which was remarkable as the first work written by a professed astronomer in which an astronomical explanation of an Ice age was put forward and defended. As the influence of these books upon popular opinion, and even perhaps upon some scientific men, may prove very misleading and mischievous, perhaps you will allow me a little space in which to discuss Sir Robert Ball's work.

The book was preceded by much advertisement, in which we were told not only that it contained an entirely new view of the subject, but that an astronomical basis of the Ice theory was at last securely established.

When the book itself was published, it appeared also that the new matter in it consisted of "a law, hitherto unsuspected, regulating the distribution of heat between summer and winter in either hemisphere." Thus on page 113 the author says: "*I discovered* the law of distribution of sun heat on a hemisphere between the two seasons into which the year is divided by the equinoxes." Again he says: "*I enumerated and proved* that law of the distribution of sun heat between the two seasons, which I have already referred to as the cardinal features of this little book" (*op. cit.* 113.) Again, in the appendix he says: "The following is the calculation often referred to in this book, and in which *for the first time*, so far as I know, the astronomical facts relating to Ice ages have been correctly given." Lastly, he says: "If it should prove that the facts which these numbers imply have not been given by any previous writer, *then their announcement is the novelty in this book, the one central feature by which it is to be judged.*" Sir Robert Ball afterwards speaks slightingly of Herschel and Croll for having ignored this law.

It was very soon pointed out in a review of his book that this particular law which Sir R. Ball claimed to have discovered had been already enunciated and published by Wiener.

The fact might easily have escaped any one else but a writer who was himself a mathematician writing expressly on this very point, which was the justification of his book. Let that pass, however.

It seems to some of us that when the Astronomer Royal for Ireland had had this pointed out to him, he ought at once to have written to the scientific papers correcting his mistake, and doing justice to the real discoverer of the law, and that the book itself should not have been issued again without this correction appearing in it, for the publication of the supposed discovery was the *raison d'être* of the book.

Nothing of the kind has happened, however, and the only reference that I know of the mistake by its author is in an appendix to a book published in 1893, entitled "The Story of the Sun," in which no reference whatever is made to the claims set up in 1891, but the law in question is simply referred to as "Wiener's law," as if everybody in the world must know that Wiener and not Ball had discovered it. Meanwhile, "The Cause of an Ice Age" is not cancelled or withdrawn or corrected, but is being continually issued with all its exploded claims.

What I have just written refers merely to a claim to have discovered a law which was discovered by some one else, and to the amenities which generally regulate our conduct when we are shown in such a case to have done another man an injustice. But this is a very small matter. A much more important matter remains.

The law which Sir R. Ball claimed to have discovered is an indisputable one. No one doubts it, or could doubt it. What most people who have examined the problem say, however, is not that the law is not a perfectly good one, but that it has nothing whatever to do with the question of an Ice age. The law in question is briefly, that the quantity of heat received by either hemisphere of the earth in summer is to that it receives in winter in the ratio of 63 to 37. This is an invariable ratio, true at all times, and true under all conditions of eccentricity of the orbit. It never varies. It was the same millions of years ago, so far as we know, as it is now, and so it will remain. It is therefore a *constant* factor in the problem, and being a *constant* factor it cannot be the cause of *variability* of climate. If, as we are told in the book over and over again, this particular proportion is the cause of an Ice age, we must be living in an Ice age now, and we must always have been in an Ice age. Therefore the law in question was not only not new, but it is an absolutely irrelevant law so far as the problem at issue is concerned. Whether the particular numerical ratio was present to the minds of Herschel and of Croll when they wrote on the problem, is quite immaterial; and being so, the whole *raison d'être* of Sir R. Ball's book is gone, and so far as we know there is not a single material factor of the problem discussed by Sir Robert Ball which was not present to Croll when he wrote "Climate and Time" and his other works.

Lastly, Sir Robert Ball, following in the wake of Croll, has subjected the various facts and conditions, both astronomical and meteorological, which in his view induced an Ice age to analysis, and has reached certain conclusions which he has emphasised in his later work, "The Story of the Sun." This analysis has been criticised and examined by more than one person, but with especial closeness of reasoning and conclusiveness by one of Sir R. Ball's own pupils, a distinguished Fellow of Trinity College, Dublin, Mr. Culverwell. His criticisms have appeared in NATURE and in the *Geological Magazine*.

In the view of those who have read these criticisms, they are simply crushing. No more complete and acute dissection and destruction of a scientific argument has appeared for many years.

This criticism was originally read at the British Association, in the presence of Sir R. Ball himself, who made no attempt whatever to answer it, but (mistaking his audience) merely gave vent to some jocular remarks. The Lowndean Professor at Cambridge cannot turn the flank of serious criticism by ill-timed jokes. Since then he has not, so far as I know, answered his critics in any way, or tried to justify his riddled arguments, and the books in which they are contained are being sold, and their conclusions are being quoted as if they were sound instead of being absolutely untenable.

If Sir R. Ball were an ordinary person, a free lance in literature and science, he might say anything and publish anything with impunity, and might refuse to answer criticism from any quarter; but he was once Astronomer Royal for Ireland. He now fills the chair at Cambridge once occupied by Adams. He cannot write without in some way committing that chair and that University by his opinions; and his principal critic is not an obscure scribbler, but a mathematician as accomplished as himself. Is it right or decent that, under these circumstances, he should continue to publish, with his name on the title-pages, works such as those I have described? Ought he not either to at once confess his mistakes, to answer his critics; or if he cannot do this, to withdraw books which have done some harm to thoughtless people, which have brought no credit to the chair he fills, nor to the University of which he is a Professor; and which have given rise to a good deal of angry comment among those who do not understand a man of science, of real distinction, remaining, for a day longer than he can help, the foster-father of what has been shown to be wrong either in fact or in argument?

I do not think Sir John Lubbock can know the facts of the case, or he would not permit his name to appear as the godparent of a book thus flyblown; nor should its publishers continue to issue it, and this not because the book contains mistakes—all books do that—but because its mistakes have been pointed out, and because its author is a great deal more than Sir Robert Ball, and cannot therefore escape the penalty of such a position.

The Athenæum Club, October 4. HENRY H. HOWORTH.

MacCullagh's Theory of Double Refraction.

An attempt has recently been made by Mr. Larmor to resuscitate MacCullagh's dynamical theory of double refraction (Brit. Assoc. Rep., 1893; *Phil. Trans.*, 1894, A, part ii.), but on examination this theory appears to me to infringe one of the fundamental principles of dynamics, viz. the principle of angular momentum.

Whatever the constitution of the medium may be, the forces which act upon any element consist of two distinct classes: (1) forces due to the action of contiguous parts of the medium; (2) forces arising from causes external to the element. The forces comprised in the first class are usually termed stresses; they act upon the surface of the element, and are completely specified by the nine quantities X_x, X_y, &c. The forces comprised in the second class act upon each element of mass, and arise from attraction or repulsion due to external causes or to the action of the medium upon itself. These forces, from whatever cause they may arise, are capable of being compounded into a single force along a line through the centre of inertia of the element, and a couple about some axis through this point. In ordinary gravitating matter the couple vanishes.

The equations of motion of the element in terms of the stresses and the *force constituent* of external action are the analytical expressions for the principle of linear momentum; but this principle is not sufficient to determine the motion of the medium—it is further necessary to satisfy the principle of angular momentum, and any theory which violates the latter principle is dynamically unsound. Now the principle of angular momentum requires that three relations of the form $X_y = Y_x$ should exist between the six shearing stresses, thereby reducing their number from six to three, except in the following two special cases. The first case occurs when the medium, previously to being disturbed by the passage of a wave of light, is *not at rest*, but possesses an independent angular momentum; that is to say, the medium is what has been termed a *gyrostatic* one. The second case occurs when the resultant of the external forces which act upon the element consists of a *couple* as well as a force. In the first case the kinetic energy of the disturbed motion of an element will not be proportional to the square of its velocity of translation, but will contain a term depending on the gyrostatic momentum: whilst in the second case the potential energy must necessarily contain a term due to external action.

Mr. Larmor assumes that the kinetic energy of an element is proportional to the square of its velocity of translation, so that the medium he considers is not a gyrostatic one; whilst the potential energy is supposed to be a quadratic function of the rotations, and he obtains his equations of motion by means of the principle of least action. Now, as we have pointed out, the potential energy of an element *may* consist of two distinct parts, viz. one due to deformation, and the other due to the action of external causes; and it is quite legitimate to assume *by way of trial* that the former part contains rotational terms. But it is well known that a quadratic expression which contains rotational terms will not satisfy the conjugate relation between the six shearing stresses, and consequently the principle of angular momentum will be violated, unless every element of the medium is under the influence of some system of forces, of the kind belonging to the second class, the couple constituent of whose resultant *does not vanish*. The potential energy ought therefore to be of the form $W + V$, where W is the portion due to deformation, whilst V is the portion due to external causes which supplies the couple which is necessary in order to prevent the principle of angular momentum being violated; and unless Mr. Larmor is able to surmount this difficulty, I am at a loss to understand how his paper is an improvement upon theories which are at any rate *dynamically sound*, whatever other imperfections they may possess. The question is one which cannot be disposed of by pages of vague and obscure generalities, but requires a detailed and careful mathematical investigation for its elucidation.

A. B. BASSET.

Holyport, Berks, October 3.

The Southern Carboniferous Flora.

So far as I am aware, Dr. Kurtz's paper on the newly discovered Carboniferous Flora in Argentina had not been noticed in print in this country until the appearance of the number of NATURE for September 26, which contained a note (p. 523) giving a brief abstract from the translation published in the Records of the Geological Survey of India. The circumstance that the original paper, which appeared nearly a year ago, was in Spanish, may have caused its being overlooked.

The subject of the ancient Southern floras is naturally unfamiliar to most European geologists, and I hope I may be allowed to point out why the present discovery is important. It completes a mass of evidence gradually accumulated. It is, of course, well known that several successive floras of Upper Palæozoic and Lower and Middle Mesozoic Age have been found associated with beds mainly of freshwater origin, some of which combine valuable coal seams, in India, Australia, and South Africa. The most ancient of these beds in Australia and South Africa contain certain plants, amongst them a *Lepidodendron*, allied to the ordinary Carboniferous flora of Europe and North America. From the upper beds in all the three regions named, Ferns, Cycads, and a few other plants have been obtained that are related to the Rhætic and Jurassic types found in European rocks. Between the upper and lower plant-bearing strata in South Africa and Australia, and beneath the upper series in India, are found beds, with coal seams in places, containing by far the most remarkable flora of the whole, the Glossopteris-flora, as it has been called. The particular interest attaching to this flora is mainly due to two circumstances. (1) It is clearly Upper Palæozoic, for in Australia the coal measures containing it are interstratified with marine beds abounding in carboniferous fossils, and yet it differs radically from any known European or North American flora of that age. (2) The basal beds, in India, Australia, and South Africa, are boulder beds, resembling the Pleistocene glacial boulder clay more than they do any other formation.

Now in Argentina the occurrence of the Southern Jurassic or Rhætic flora has been known for some years, and Prof. Derby has called attention to the presence in Southern Brazil of a great boulder bed, that very probably corresponds in character and geological position to the Talchir beds of India and the Dwyka beds of South Africa. More recently traces of the ancient Lepidodendron flora have been discovered in Argentina, and some additions to that flora are described in Dr. Kurtz's paper. But the important announcement in this paper is the discovery in Argentina of three Indian lower Gondwána plants, *Neuropteridium validum*, *Gangamopteris cyclopteroides*, and *Noeggerathiopsis hislopi*, all three associated in India with the Karharbári coal-seams near the base of the Lower Gondwána. Two of the species are also found or represented by closely allied forms in Australia and South Africa. In Argentina, as in India, Australia, and South Africa, there is a remarkable absence in this particular flora of forms characteristic of the Upper Palæozoic of Europe, no representative of Lepidodendron or Sigillaria occurs, and the Ferns, Cycads, and Equisetaceæ that constitute the flora are related to European Mesozoic types.

It is difficult to understand how two floras differing from each other far more widely than do any two continental floras living on the earth's surface at the present day, can have coexisted unless there was, for a long period of geological time, a great southern continent—the Gondwána-land of Suess—isolated by a wide sea, probably an ocean, from the land that occupied in Carboniferous and Permian days so wide an area in the northern hemisphere. The importance of the new discovery is the immense extension that it gives to Gondwana-land, and the proof it affords that the region with its flora extended to the western hemisphere, and included a part, at all events, of South America. This appears to indicate that a considerable area now occupied by ocean in the southern hemisphere was land in the Carboniferous period. Further research is needed to show whether the various tracts of Gondwana-land were connected by a South Polar land area.

W. T. BLANFORD.

October 4.

About a certain Class of Curved Lines in Space of [illegible] Manifoldness.

The class of curves [illegible] considered is defined by the following [illegible]: A curve of that class situated in plane space of n [manifol]dness is cut by a S_{n-1} in n different [or] coinciding [poin]ts. In the plane it is therefore a conic, and in space a [illegible].

[If th]rough $n-1$ of its points a pencil of S_{n-1} is drawn, then [each] element of that pencil cuts out of the curve [one] additional [point], and has with a straight line one point in common. The [coordinates] of the curve must therefore be expressible as [rational] functions of one parameter. If any fixed pyramid A_1, A_2 . . . A_{n+1} is [selected] as pyramid of reference, then any [poin]t P of the curve

$$(\Sigma\chi) \;.\; P = \chi_1 A_1 + \;.\;.\;.\; + \chi_{n+1} A_{n+1},$$

[supp]ose χ to be the homogeneous coordinates of P; and it [follo]ws

$$\chi_1 = R_1(\lambda, \mu) \;.\;.\;.\; \chi_{n+1} = R_{n+1}(\lambda, \mu).$$

[Her]e the R are homogeneous and integer functions of the [λ], μ. To ensure that a S_{n-1} has n points exactly with the [cur]ve in common, necessitates that the degree of the R is $= n$.

It follows from the definition that no S_k can have more than [$k+$]1 points in common with the curve (unless the curve is [who]lly contained in the S_k), as otherwise through this S_k and [$n-k-1$] additional points belonging to the curve a S_{n-1} might be [const]ructed, having more than n points in common with the [curve].

The curve is uniquely determined by any $n+3$ of its points; [and] between any $n+4$ of its points a certain condition is fulfilled (from which for $n=2$ the well-known Chasles and Pascal theorems for conics are easily deducible). To construct [thi]s condition and verify this proposition, let us return to the [art]icle entitled "Metrical Relations," &c., of NATURE, August [8]. There it was pointed out that a point and a S_{n-1} may have [a pe]culiar situation in regard to a pyramid of n manifoldness, by [vir]tue of which to each point of the S_n corresponds one S_{n-1}, [and vice vers]a. It is not difficult to verify that when the co[ordinat]es of the point in regard to the pyramid are

$$a_1 \;.\;.\;.\; a_{n+1},$$

[the]n the coordinates [χ] of the points of the S_{n-1} satisfy the [equatio]n

$$\frac{\chi_1}{a_1} + \frac{\chi_2}{a_2} \;.\;.\;.\; + \frac{\chi_{n+1}}{a_{n+1}} = 0.$$

[If] point and S_{n-1} have that relation to a pyramid, then they [ma]y be called pole and polar to it. It will be remembered that [the co]nstruction of pole to polar, and *vice versa*, is a purely [projecti]ve one, by means of cuts of plane spaces, &c. The [rel]ation of $n+4$ points of the curve to each other is now, [that] the polars of any three with regard to the pyramid of the [oth]er $n+1$ have a S_{n-2} in common.

[Indeed], let A_1 . . . A_{n+1} be $n+1$ points of the curve, and [illegible] the other points, also

$$\Sigma\chi \;.\; P = \chi_1 A_1 + \;.\;.\;.\; + \chi_{n+1} A_{n+1} \text{ and } \chi = R(\lambda, \mu).$$

[Th]en, A_1 being a point of the curve, R_2 . . . R_{n+1} must have a [common] [illegible] point; and the same is true for R_1 R_3 . . . R_{n+1}; [illegible] R_1 . R_2 . . . R_n [illegible]. It is therefore easily seen that the [coordinates] of P may be put into the form

$$\chi_i = \frac{1}{\gamma_i\lambda + \delta_i\mu}, \text{ where } \gamma_i \text{ and } \delta_i \text{ are constants.}$$

The polars of P form, therefore, a pencil; that is, they have a [illegible] in common.

[illegible] are projected from any one of its [illegible] S_{n-1}, they form a curve of the class considered in [illegible] verified from the representation of the co[ordinates] by [a] parameter. For $n=1$ the curve becomes a [illegible] form a homographic range with that [illegible] points are the representatives of the [illegible]. [illegible] four points of the [illegible] S_{n-1} of [illegible].

[illegible] always into straight [illegible]. [illegible] It is also obvious, that each [illegible] a conic and [illegible] point in common that is not situated [in] the same plane), or into three straight lines, of which one has one point in common with each of the other two.

In each point of the curve there is one straight line, that has two coinciding points in common with the curve, and one plane, that has three points of intersection which all coincide, &c. They may be called tangent lines, planes, &c., of the curve. Cut the curve by a S_{n-1}. If the n points of intersection are distinct, draw the n tangent S_{n-1} through them; and if only $n-2$ are distinct, and 2 coincide, draw the $n-2$ tangent S_{n-1}, and the one tangent S_{n-2}; and so on.

The point of intersection of these plane spaces may be called the *pole* of the original S_{n-1} to the curve; and this one, the *polar* of that point. The polar of any point of the polar passes the pole. Let the pyramid of reference be chosen so that the equation of the curve is

$$\chi_1 = \lambda^n \quad \chi_2 = \lambda^{n-1}\mu \;.\;.\;.\; \chi_{n+1} = \mu^n.$$

The S_{n-1} may satisfy the equation

$$p_1\chi_1 + \;.\;.\;.\; + p_{n+1}\chi_{n+1} = 0.$$

The n points of intersection are then given by

$$p_1\lambda^n + \;.\;.\;.\; + p_{n+1}\mu^n = 0.$$

Their roots may be

$$\lambda : \mu = \alpha_1, \; \alpha_2 \;.\;.\;.\; \alpha_n.$$

Through $\chi_1 = \alpha_i^n$, $\chi_2 = \alpha_i^{n-1}$ . . . the tangent S_{n-1} (whose coordinates may be ξ) $a_1\xi_1 + \;.\;.\;.\; + a_{n+1}\xi_{n+1} = 0$ will be such that

$$a_1 = 1 \quad a_2 = n\beta \quad a_3 = (n)_2\beta^2 \;.\;.\;.\; a_{n+1} = \beta^n,$$

where β is a parameter, whose value is found $= -\alpha$. The point of intersection of the n S_{n-1}, whose equations are

$$\xi_1 - n \,.\, \alpha_i \quad \xi_2 + (n)_2 \,.\, \alpha_i^2 \quad \xi_3 - \;.\; \pm \alpha_i^n \xi_{n+1} = 0$$

is obviously

$$\xi_{n+1} = p_1 \quad \xi_n = -\frac{p_2}{n}$$

$$\xi_{n-1} = \frac{p_3}{(n)_2}, \;\; \&c.$$

(on account of the equation satisfied by the α).

If ξ_i is any point, and χ_i any point on its polar, the equation exists

$$\xi_{n+1}\chi_1 - n\xi_n\chi_2 + (n)_2\xi_{n-1}\chi_3 - \;.\;.\;.\; = 0,$$

which is symmetrical, and therefore proves the proposition.

The polar to a line joining two points is the cut of their polars; and so generally. It is therefore possible to speak of the polar, or pole, of any plane space, in regard to the curve. The two are united only when the two sets of coordinates are equal, that is, when they satisfy a condition of the second degree. Pole and polar cut a straight line in involution, as immediately follows from the symmetry of the equation connecting them. The double points of the involution are the points in which the straight line cuts that surface of the second order.

Much more could be said concerning this class of curves, the properties of which are so much like those of the conics; but I hope that what has already been mentioned will be found sufficient to interest mathematicians in their existence.

London, September 6. EMANUEL LASKER.

The Freezing Point of Silver.

THE subject of high temperature thermometry has recently attracted considerable attention, and on account of the ease with which silver can be obtained in a pure state, coupled with its great thermal conductivity, the freezing point of this metal has been suggested as a standard temperature. We therefore wish to call attention to an error into which we believe M. le Chatelier has fallen with regard to this constant. In the *Zeitschrift für Physikalische Chemie*, Band viii. p. 186, he says that the melting point of silver can be lowered by as much as 30° through the absorption of hydrogen; again, in the *Comptes rendus* for August 12, 1895, he states that the melting point of this metal is lowered by a reducing atmosphere. He therefore recommends that when the melting point of silver is used as a fixed point in calibrating pyrometers, the experiment should be performed in an *oxidising* atmosphere. This conclusion is contradicted by Prof. Callendar's experiments and by our own, for in the *Phil. Mag.*, vol. xxxiii. p. 220, Callendar shows that the freezing point of silver is lowered and rendered irregular by an oxidising atmosphere; and our own results confirm this

conclusion. But serious doubt having been raised on this point by so high an authority as M. le Chatelier, we have thought it right to make further experiments.

These experiments convince us that the freezing point of molten silver is lowered and rendered variable when the surface is exposed to the air. We also find that by blowing oxygen through the molten metal, the absorption of this gas is sufficiently great to lower the freezing point 20°. Moreover, when the oxygen is removed by the action of either carbon, coal gas, or hydrogen, a constant maximum freezing point is reached. Further, if the atmosphere of hydrogen, or coal gas, be replaced by carbon dioxide, there is no change in the freezing point, whilst if nitrogen be used to sweep out the hydrogen, there is a slight fall. In neither case does the removal of the hydrogen bring about a rise, as should be the case on M. le Chatelier's hypothesis.

Another strong reason for believing that the true freezing point of silver can only be obtained in a reducing atmosphere, is to be found in the remarkable constancy with which a considerable mass of pure silver maintains its temperature from the moment that freezing commences until the whole is solid, provided it has not been exposed to the action of free oxygen. It is also noteworthy that in a reducing atmosphere the melting and freezing points are identical.

Impure substances do not as a rule behave in this way, and hence it is improbable that the silver can contain dissolved hydrogen. In an oxidising atmosphere the freezing point is less sharply marked, and the silver behaves as if it were impure.

These are our reasons for venturing to differ from M. le Chatelier, and we hope that he will further examine the question.

F. H. Neville.

Plant-Animal Symbiosis.

In your issue of August 22, 1895, Mr. Schwarz describes his finding in South Africa some ants inhabiting the thorns of a mimosa tree, by which he evidently means a species of *Acacia*. This symbiosis is well known out here, and probably also in Europe, as will be seen by a reference to Schimper's "Wechselbeziehungen zwischen Pflanzen und Ameisen im tropischen Amerika," p. 48. I first observed ants inhabiting the thorns of *Acacia horrida* in the neighbourhood of Grahamstown about six years ago. I also found them near Port Alfred. As far as my repeated observations go, the partnership between the ants and the trees is a very one-sided one.

The former receive shelter and food from the trees, whereas I have failed to find that the latter derive any advantage from it. This last conclusion is not surprising, as, firstly, amongst the "mimosa"-scrub near Grahamstown, one only finds here and there a tree the thorns of which are inhabited by ants, and as, secondly, in some years *all* individuals of *Acacia horrida* are completely denuded of their foliage over wide areas by caterpillars. Moreover the ants (of which I found two different kinds) are, as Mr. Schwarz rightly observes, not at all aggressive, whereas Belt showed that the little ants living in the hollow thorns of *Acacia sphaerocephala* in Central America are very pugnacious, and protect the plant against browsing mammalia and insect enemies.

The two cases are, therefore, very different from one another.

Albany Museum, Grahamstown, South Africa,
September 16.

The Recent Dry Weather.

With reference to the recent remarkable weather, both at the commencement of the year and during September, it is worth while calling attention to the climatological period of about thirty-five years, which Prof. Bruckner, of Berne, pointed out as existing relatively to the years or groups of years characterised by marked cold or heat, as mentioned in vol. xliii. p. 163 of Nature. He therein indicated the years 1700, 1740, 1780, 1815, 1850, and 1880 as centres of cold periods, while the years 1720, 1760, 1795, 1830, 1860 (and now 1895) appear as centres of warm, dry periods. The coincidence for the present year is certainly remarkable, and merits attention as to the causes which underlie these periodic fluctuations of weather.

Dublin, October 11. J. P. O'Reilly.

The Genus "Testacella."

In Nature for last year the writer gave a list of the localities for *Testacella scutulum* which had come under his notice. With a view to making this list more complete, and to obtaining a more definite idea of the distribution of the various species of the genus in the British Isles, the writer would be greatly indebted to any reader of Nature who could forward to him, localised specimens of *Testacella*, alive, or preserved in alcohol, the present month being a likely one for the coming above ground of these slugs, which should now be found under logs and stones in the neighbourhood of rich garden soil.

Wilfred Mark Webb.

"Holmesdale," Brentwood, Essex.

The B.A. Committee on Coast Erosion.

In the reference, in your number of Oct. 3, to "Geology at the British Association," the statement as to the Coast Erosion Committee, in their final report, recommending a "Departmental Committee of the House of Commons," to inquire into the subject, is taken from the "first proof" of the report, which was drafted by myself as surviving Secretary. The suggestion has *not* been adopted by the majority of the Committee, who considered their duty did not extend to drawing up and formulating recommendations. This termination I regret, as when the Association adopted my suggestion in 1881, to appoint this Committee, I hoped it would have had a practical outcome, leading to the conservation of our coasts.

Charles E. De Rance.

A Substitute for Sulphuretted Hydrogen.

In your Notes of February 14 last, you state that ammonium thio-acetate has been found to be a satisfactory substitute for sulphuretted hydrogen in chemical analysis. Can any of your readers tell me where I can obtain it? I cannot find it in catalogues of chemical manufacturers. Rusticus.

THE GRAPHICS OF PIANO TOUCH.

Much trouble has been taken in order to construct an apparatus that will reproduce graphically the effects of touch in keyed musical instruments. The experiments are most easily made with the piano, and have therefore been tried on that instrument.

Recently a most interesting article appeared in the *Revue Scientifique*, written by MM. Binet and Courtier, who have studied this subject closely, and have made many experiments with their apparatus. They have treated the matter very fully in their article, of which the following is a *résumé*:

When a certain point of perfection has been attained in piano playing, it becomes very hard to distinguish inequality of touch; yet, owing to the varying strength of the fingers, it is only with much practice that perfect equality is possible. As will be seen further on, involuntary movements and irregularities, scarcely perceptible to the ear, are shown by the graphical method.

The apparatus (Fig. 1) is quite simple in construction, and consists chiefly of an india-rubber tube, placed under the key-board, united at its two extremities by a registering drum, also of india-rubber. When the notes of the piano are played, the pressure on the tube causes a wave of air to be sent through it into the drum, upon which is attached a pen that in the ordinary way is made to record its movement on a moving roll of paper. The wave makes the drum vibrate, which in its turn jerks the pen, thus causing irregular marks to be left on the paper. The board on which the tube rests is regulated by means of wedges adjusted by a screw, the board being either lowered or raised. When raised it almost reaches the notes of the piano, and in this case the registering action takes place; but if it is lowered, the whole apparatus is disconnected from the key board.

When no notes are being played, and the registering drum is connected, *i.e.* the board is raised, merely a straight line is drawn. In Fig. 2, first *a* is struck, then two notes with *b*, then three notes with *c*, and so on. It

is difficult to tell whether the mark made for each additional note is the same length, for when three notes are struck they may not each be struck with the same force. In the second case (Fig. 2) one note is struck, held down and another struck, and so on, the previous notes always being kept down. The effect produced is

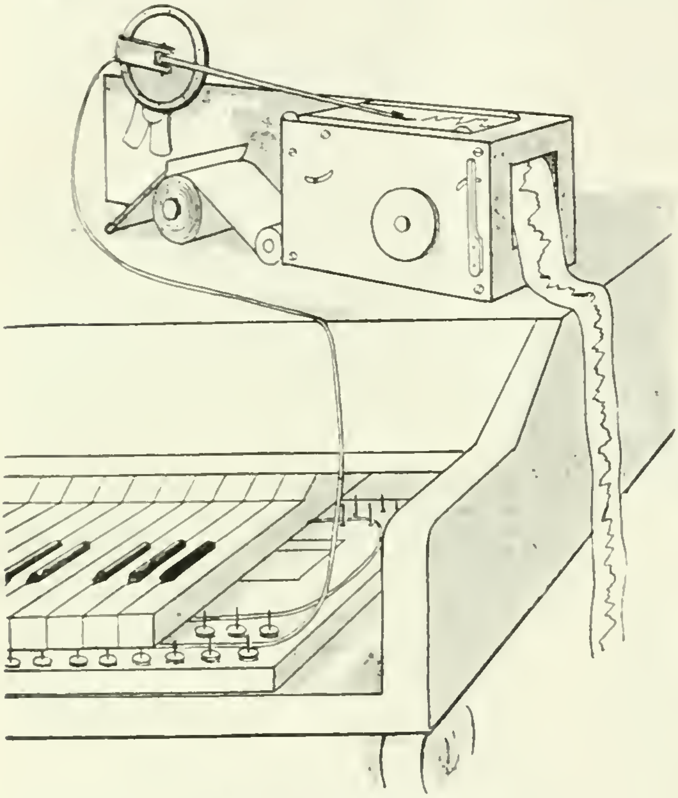

FIG. 1.—Illustration of the apparatus.

curiously like a flight of stairs, but the height of each stair is not absolutely equal. This proves that the apparatus is sufficiently sensitive to show, by the height of the lines, the intensity with which a note is struck.

With regard to *time*, it is reproduced with the utmost precision, and it is in order to guarantee accuracy that the ... connected to the drum at both ends, otherwise the notes situated near the end which was not connected, would be farther removed from the drum than the others, and this would cause a delay in their being registered.

The graphical *form* ought theoretically to be an imitation of the movement played, but this result is not often achieved. When very quick passages are being played, the strong wave of air shakes the drum so forcibly, that

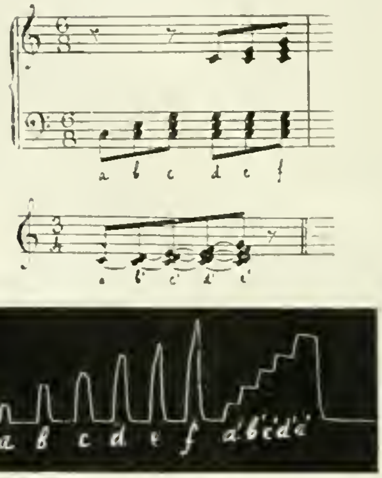

FIG. 2.—Effects produced: *a*, in striking one note, and *b*, *c*, *d*, *e*, *f*, in striking chords of two up to six notes; in the second case, *a'*, *b'*, *c'*, *d'*, *e'*, in playing five successive notes, and keeping them down.

FIG. 3.—A represents effect without the insertion of the diaphragm, B the effect with the diaphragm.

the pen ceases to act properly. Much trouble has been taken to devise a way of lessening the force of the wave; amongst other materials, cotton has been inserted into the tube, but these experiments were not entirely successful. It has been found that placing a diaphragm with a small hole in the tube, lessens the force of the wave of air very considerably, and to a certain extent prevents the drum vibrating too strongly.

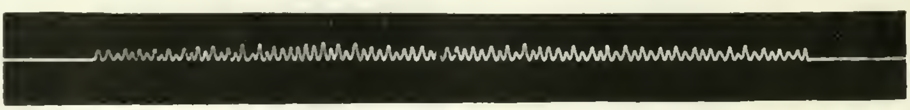

FIG. 4.—Shake executed with first and second finger.

FIG. 5.—Effects produced by an irregular shake.

The effect produced without and with the diaphragm will be seen in Fig. 3.

Figs. 4 and 5 illustrate shakes, and show clearly the importance of equality of touch: they show, too, how precisely the apparatus reproduces any irregularity.

Many questions have to be considered with regard to quick playing, but one of the most striking features is that the more quickly the notes are played, the more the force of the movement diminishes, until finally a certain stage is reached, when the amplitude ceases to vary.

Let us now consider the advantages of the instrument; they are threefold.

(1) Dealing with its advantage from the psychological point of view, it is found that the voluntary movements of the pianist can be observed without putting him to any restraint or embarrassment, for the small tube does not affect the resistance of the notes, nor is the exterior of the piano altered.

(2) For teaching purposes the device has been of great use. The record on the roll of paper shows the faults so precisely, that although they are scarcely perceptible to the ear, there is no denying their existence.

(3) We are well aware that written music cannot show every slight change in the time the composer might desire. By applying the graphical method, this difficulty is eliminated, and the time will be reproduced with the smallest details.

THE NEW METEOROLOGICAL STATION ON MOUNT WELLINGTON.

A VIEW of the new meteorological observatory on Mount Wellington, Tasmania, is shown in the accompanying illustration. As we announced in a previous issue (July 25), the observatory was begun in May last, and it will be to the southern hemisphere what the Ben Nevis and other high-level observatories are to the northern. Mount Wellington is about four miles distant from Hobart, and rises almost directly from the level of the sea. The station is supplied with a "Fortin" mountain barometer, "Richard" barograph and thermograph, dry-wet, and maximum and minimum, thermometers, as well as a "5-inch" gauge with extra deep rim for retaining snow. Similar instruments are in use at the Springs (2495 ft.) and at Hobart, 160 feet above sea-level. Mr. Clement L. Wragge, Superintendent of the Chief Weather Bureau, Brisbane, has organised the stations. Very valuable results, bearing upon the distribution of pressure, temperature and humidity attaching to anticyclonic and cyclonic systems through vertical sections of the atmosphere in the northern and southern hemispheres respectively, will probably be forthcoming when the Mount Wellington and Hobart results appear and are discussed side by side with those obtained at Ben Nevis and Fort William. Except for a few degrees of latitude, Mount Wellington and Hobart are geographically and physiographically almost the very counterparts in the southern hemisphere of Ben Nevis and Fort William in the northern. Mr. Wragge has entirely reorganised the Tasmanian Government Meteorological Service on federal principles in direct connection with the Queensland Weather Service, and he was enabled to perform this work through the courtesy of the Queensland Government, who allowed him as their officer to render federal aid in the cause of science to the sister colony. Mr. H. C. Kingsmill has charge of the Tasmanian section.

The barometer cairn, now a larder, and barometer transferred to house (4166 feet).

The Observatory, Mount Wellington (4166 feet above sea-level).

DR. E. VON REBEUR-PASCHWITZ.

E. VON REBEUR-PASCHWITZ was born in 1861, and died, after an illness of ten years, on the first of the present month. In many ways he always seemed to me to resemble our incarnation of the ideal man of science. He had Darwin's lovable nature, as well as his modesty and utter carelessness of his own fame. But the likeness was closest in the unceasing energy with which he laboured, in spite of the constant suffering that would have made many stronger men feel their life's work was done.

For some time von Rebeur-Paschwitz was a Privat-docent in Astronomy at the University of Halle. His first notable achievement was, I believe, the modification of Zöllner's horizontal pendulum, the two springs by which it was supported being replaced by agate cups resting on fine steel points. The earlier investigations with this instrument were intended to be of an astronomical character, but its wonderful sensitiveness to the pulsations of distant earthquakes soon became apparent, and he was gradually led to give more time to their study, until he became the chief authority on this fascinating branch of seismology. On two occasions he contributed articles to NATURE on this subject (vol. xl. pp. 294-295; vol. li. pp

2 S 211), and, at the request of the Earth Tremors Committee of the British Association, he wrote an admirable summary of his results up to the middle of 1893. As this is readily accessible, it is unnecessary to enlarge upon his achievements here. I will merely add that since that date he has written several papers on earthquake-pulsations in Petermann's *Mittheilungen* and the *Astronomische Nachrichten*. His last memoir, and one of the most valuable, has just been published in Gerland's *Beiträge zur Geophysik*.

For several months before his death, von Rebeur-Paschwitz was occupied with a scheme for the organised study of earthquake-pulsations all over the globe. The suitability of his horizontal pendulum for this purpose had received ample proof, and nothing but the want of health seemed likely to prevent the fulfilment of his plans. These, no doubt, will be carried out by other, if less skilful, hands; but to him will belong a great part of the credit for any results that may be attained. Dying at thirty four, he had done work which most men of twice the age might regard with satisfaction as the fruits of a well-spent life. CHARLES DAVISON.

CHARLES V. RILEY.

CHARLES V. RILEY, M.A., Ph.D., whose death on the 14th ult., in consequence of injuries received in a fall from a bicycle in the streets of Washington, was announced in these columns on October 3, was an Englishman, born at Walton-on-Thames in 1843. He emigrated to the United States at the age of seventeen, and settled, as we learn from the *Garden and Forest*, on a farm in Illinois. Like so many other Americans, who have since made a reputation in science, he served as a soldier in the civil war. Subsequently, after some experience as a journalist, he was appointed State Entomologist of Missouri, a position he occupied nearly ten years. During this period he did excellent work in the investigation of the life-histories of insects injurious to plants, and experiments to discover the most effectual means of destroying them. But one of his earliest papers was on a new genus *Pronuba* of the Tineidae, and the part it plays in the fertilisation of *Yucca*.[1] This was an important and interesting contribution to biological science. In 1878 he accepted the post of Entomologist to the United States Department of Agriculture at Washington, where, in the words of the authority cited above, he practically supervised all the entomological work of the Government until his resignation last year. The valuable results of the investigations and experiments conducted by him and his staff, were in part published in occasional bulletins, of which thirty-two appeared between 1883 and 1894, and partly in the now familiar periodical entitled *Insect Life*, which was established in 1888. Six volumes appeared under his editorship. Dr. Riley was an indefatigable worker, and his organising and administrative qualities were well exemplified in the department which he so successfully developed. W. B. H.

NOTES.

I[illegible] in order to enable the Berlin Academy of [illegible] complete edition of Kant's works, the Govern[illegible] consented to place at its disposal for a [illegible] manuscripts belonging to the University [illegible]

[illegible] *[illegible] Medical Journal*, the New York [illegible] has purchased thirty five acres of land near [illegible] experiment station is to be established. [illegible] stocked with cows, horses, sheep, [illegible] for the production of diphtheria and cancer antitoxins. The situation is healthy, and in the grounds there will be a house in which some of the patients of the Institute will be treated. A new station, to be known as the Pasteur Station, will be established on the Erie Railroad, close at hand.

WE regret to notice the following announcement in *Science*:—"Prof. Ernst Ritter, whose appointment as assistant professor of mathematics in Cornell University was recently announced, died on September 23, of typhoid fever, on his arrival in America from Germany. Ernst Ritter was born at Waltershausen, Germany, on January 9, 1867. He spent twelve years at the Gymnasium at Gotha, and afterwards studied mathematics and natural science under Thomas, at Jena, and under Klein and Schwartz, at Göttingen. In 1890 he passed the Government teacher's examination with the highest distinction, after two years of pedagogical work at Cassel, and at the Wohlerschule in Frankfurt. He took the degree of Ph.D., *summa cum laude*, at Göttingen in 1892. In 1893 he was appointed assistant to Prof. Klein, and began to devote his entire time to mathematics, contributing regularly to mathematical periodicals. Last year he lectured on geometry and the theory of automorphic functions, in which he was an authority. He was appointed to his Cornell professorship last June."

WE learn from the *Journal* of the Franklin Institute that the German Hygienic Association offers a prize of 1200 dols. for a research essay on the efficiency of electric heaters. The programme is as follows: "The heat given out in heating installations by heaters in their various forms and modes of use is to be ascertained. The investigations are to be described in detail in respect to the arrangement of the heaters, the nature of the heating agents, and the observations made; and they are to be illustrated by drawings. The heating values obtained are to be stated in units of heat given off per hour per unit of surface. In the case of heat given out to air, the investigations must be conducted with currents of air at speeds as different as possible. The heaters are to be described in detail as regards form and measurement, and the relation of their heating efficiency to their weight is also to be ascertained." Essays are to be written in German, and sent, with a motto and sealed envelope, to Prof. Konrad Hartmann, Charlottenburg, Fasannstrasse 18, before July 1, 1896. The essay will remain the property of the successful competitor, but he is required to publish it within six months, and to give the prize offerers gratuitously 300 copies. The offerers reserve the right to divide or withhold the prize.

THE display of horseless carriages, held at Tunbridge Wells on Tuesday, under the superintendence of Sir David Salomons, will do something towards the introduction of self-propelling light vehicles in England. Two carriages, fitted with Daimler motors, were shown in operation. One of these, that belonging to Sir David Salomons, weighs 13 cwt., and will run nearly two hundred miles without recharging. The motor has a horsepower of 3¾, and a speed of fifteen miles an hour can be attained on a level road, while on a gradient of one in ten a speed of four miles an hour is reached. A mechanical tricycle, worked by a petroleum motor with electric spark ignition, was shown by MM. de Dion and Bouton, of Paris. The tricycle can run at a rate of fourteen miles an hour, and only needs a fresh supply of benzine after about six hours' work. The exhibition proved the capabilities of auto-mobile carriages to a large number of spectators, and it will probably do something to bring about a change in the present vexatious Highways and Locomotives Act, which at present limits the rate of speed of self-propelled carriages to two miles an hour, and makes it necessary for a man carrying a red flag to precede the carriage as a warning of approaching danger!

[illegible]

The first series of lectures given in connection with the Sunday Lecture Society begins on Sunday afternoon, October 20, in St. George's Hall, Langham Place, at 4 p.m., when Prof. Sir Frederick Pollock, Bart., will lecture on "Tyndall as Worker and Teacher." Lectures will be subsequently given by Dr. C. W. Kimmins, Rev. Stewart Headlam, Prince Kropotkin, Mr. Graham Wallas, Mr. Wyke Bayliss, and Dr. R. D. Roberts.

Facts are always worth recording, and we publish the following note because it contains an interesting fact, which is, moreover, in accordance with other observations. The note came to us from Mr. Mata Prasad, Benares: "It was quite accidentally observed, by a stammering friend of mine, during the months of May and June last, that on moonlight nights he stammered more than on dark nights, and when he slept exposed to the rays of the moon during the month of June, he found that he stammered the most on days succeeding full moons, while a day just after the new moon, and a day before, he had not a single attack of the fit."

The organisms responsible for the production of the Japanese beverage saké are still the subject of comment and investigation. Only a few weeks ago we received a communication from Dr. Jorgensen, in which he claimed to have discovered that the mould known as Aspergillus oryzæ, employed in the preparation of sake, was capable of producing the yeast cells invariably present, and that, therefore, only one organism was responsible for the elaboration of this well-known beverage. Mr. Atkinson, who investigated this subject some years ago in Japan, could find no evidence of the transformation of the mould into yeast cells, and maintained that the mycelium and the ferment were entirely distinct. This view has been quite recently upheld by some experiments published by Messrs. Kosai and Yabe, of Tokio. They have found that in the preparation of saké two distinct organisms are required, the well-known Aspergillus and a species of yeast. These have been carefully isolated and their growth watched in various solutions, with the result that the mould only gave rise to typical mycelium growths, whilst the yeast elaborated only yeast cells, without exhibiting a trace of mould. The authors are now engaged upon carefully identifying this sake-yeast, and state that, as far as their investigations at present go, it resembles the *Saccharomyces cerevisiæ*, with which they are carrying out numerous comparative experiments.

Only those who have much to do with scientific literature know how important, and yet how much neglected, is the art of making references. No apology is needed, therefore, for reprinting in full the following rules abstracted from a paper that appeared in the *British Medical Journal*, 1895, vol. i. p. 875, by Mr. J. B. Bailey, Librarian of the Royal College of Surgeons of England. The rules can be obtained printed on a card, so that an abstractor can always have them before him. (1) The titles of all books and periodical publications should be given in the language in which they are written. (2) References should be taken from the title-pages, and not from the lettering on the backs of books. (3) Where two, or more, vols. are bound together, care should be taken that the reference is made from the right title-page. (4) Where a journal is in more than one series, the number of the series as well as the vol. and date should be given. (5) When an abstract only of a paper is referred to, this fact should be stated, and reference to the original paper given if possible. (6) Journals and Transactions should not be quoted by the date of issue, but by vol., date and page. (7) In books which have two sets of paging, care should be taken to specify exactly the pagination to which reference is made. (8) The name of the editor of a journal should not be used as part of a title unless it be necessary to distinguish between two journals with similar titles. (9) References to papers read before Societies which do not publish any separate reports of their meetings should quote the journal where the paper in question can be found. (10) In abbreviating titles care should be taken that the abbreviation shows exactly what journal is referred to, *e.g.*, *Jnl. Anat. Physiol.* does not make it clear whether an English, French or German book is quoted.

The Smithsonian Institution has recently published a series of directions for collectors, as separate portions of *Bulletin* No. 3 of the U.S. National Museum. The directions for collecting minerals, rocks, and fossils (parts H, I, and K) are written by the curators of the respective departments, and include advice not only on actual collecting, but on preparing, labelling, making sections, &c. Many of the recommendations are novel, and all cannot fail to be helpful to amateur collectors.

The *Bulletin of Miscellaneous Information* of the Royal Gardens, Kew, for September, continues the *Diagnoses Africanæ*, in which, in addition to a large number of new species, two new genera are described: *Cyclocheilon*, Oliv., belonging to the Scrophulariaceæ, and *Phillipsia*, Rolfe, belonging to the Acanthaceæ. An interesting account is given of the history of the rock-garden, based on a list of herbaceous plants cultivated in the Royal Gardens, Kew, issued by the Department.

Under the modest title of "Guide to the Collections of Rocks and Fossils," the Geological Survey of Ireland has published what is really an excellent guide to the geology of Ireland. The authors are Messrs. W. W. Watts and A. McHenry, and the price of the book is ninepence. It opens with a short introduction, explaining the principles on which is based the classification adopted in the Science and Art Museum, Dublin. Two-thirds of the book are taken up with an account of the rocks of Ireland, each of the four provinces being taken in turn. Part iii. begins with a popular account of general Palæontology, which is followed by a description of the fossils exhibited, and this by a catalogue of figured and type specimens in the museum. Finally we have an index of localities for the rocks described, that should be most useful to amateur geologists.

The Observatory of Manila has published an extensive discussion of the typhoons of the year 1894, prepared by the Rev. J. Algué, S.J. The work occupies 176 small folio pages, and is accompanied by a large number of plates showing the tracks of the different storms and concomitant data, and also contains some general considerations respecting the character of these disturbances in the extreme East. A section is devoted to the distribution of the various meteorological elements around the centres of areas of low barometic pressures at Manila during the years 1879-94. The result of this discussion shows that the distance of the cyclonic centre cannot be determined from the reading of the barometer alone; but the author describes an apparatus, which he calls a "cyclonoscope," whereby an aproximate idea of the distance of the vortex may be determined.

W. Engelmann, Leipzig, will shortly publish the collected papers of Prof. W. Roux upon the "Entwickelungsmechanik der Organismen." The work will consist of two volumes, illustrated with lithographic plates, and numerous illustrations in the text.

The sixth part of *Bulletin* No. 9 of the *Minnesota Botanical Studies* (August 1895), is entirely occupied by a very useful "Contribution to the Bibliography of American Algæ," by Miss Josephine E. Tilden. No less than 1544 separate works or papers are enumerated.

The discourse entitled "The Splash of a Drop," delivered by Prof. A. M. Worthington, F.R.S., at the Royal Institution in May 1894, has been published in book form by the Society for Promoting Christian Knowledge, with illustrations of the

beautiful phenomena described. The arrangement employed to obtain photographs of drop-splashes, and some of the results, were shown in NATURE of July 5, 1894.

DR. E. RUDOLPH, who has given much attention to submarine earthquakes and eruptions, has recently contributed a second valuable memoir on "Seebeben" to the *Beiträge zur Geophysik*. It contains accounts of more than two hundred additional shocks, and also a small map of the seismic zone of the Equatorial Atlantic. The memoir concludes with a useful list of questions for the observation of submarine earthquakes.

M. DE FONVIELLE has translated into French Lord Salisbury's Oxford Address to the British Association, and MM. Gauthier-Villars et Fils have just published the translation in their series of Actualites Scientifiques, under the title "Les Limites Actuelles de notre Science." The address is prefaced by a long introduction, in which the translator describes the circumstances under which it was given; and throughout the pages there are numerous notes explanatory of points, the importance of which might be overlooked by French readers.

A NEW volume in the Aide mémoire Series, published jointly by Gauthier-Villars and Masson, is "Polarisation et Saccharimétrie," by D. Sidersky. The volume is a handy aid to the study of polarisation and its numerous applications in analytical chemistry. The first part contains a description of the properties of polarised light, a table of the specific rotatory powers of various optically active substances, and explanations of polarising apparatus. The second part of the book is devoted to the applications of the constant of rotation to the quantitative analysis of sugars, alkaloids, &c., together with a number of tables which will facilitate the practical application of the processes described.

By the recent publication of two numbers of the *Essex Naturalist*, the Essex Field Club has brought their journal up to date. The first number (November–December 1894) includes papers on "Izaak Walton's Association with the Lea," by J. E. Harting, the "Geology of the Lea Valley," by T. V. Holmes, and on "Navestock in Olden Days," by Rev. S. Coode Hore. The second number (January–June 1895), contains a paper, by Prof. Meldola, on the "Eastern Boundary Stones of Waltham Forest," the Presidential address (in which the part played by the Club in the development of technical education in the county is explained), and a series of three papers, by Messrs. T. V. Holmes, E. T. Newton, and W. M. Webb, on the section in brick-earth at Chelmsford in which mammoth remains were recently found.

SEVERAL interesting papers are contained in the part of the *Proceedings* of the Royal Society of Edinburgh, just published (vol. xx. pp. 385–480). In "A Sketch of Lake-Dwelling Research," Dr. Robert Munro shows that over a wide geographical area, extending from Ireland to Bosnia, and from North Germany to Italy, the habit of constructing lake- and marsh dwellings was prevalent in former times. Prof. Sir William Turner, F.R.S., has a paper "On M. Dubois' description of remains found in Java, named by him *Pithecanthropus erectus*; with remarks on so-called transitional forms between Apes and Man." A paper on drops, by Mr. J. B. Hannay, summarises the work of various observers on the formation of drops, and the variation with density and chemical composition of the liquid forming them, and gives the author's own investigations upon the subject. There are also in the *Proceedings* Prof. T. R. Fraser's two papers on "Antivenine," and a paper by Prof. J. C. Ewart, "On the Dorsal Branches of the Cranial and Spinal Nerves of Elasmobranchs."

THE fourth edition, revised and enlarged, of Dr. Carl Günther's "Bakteriologie" has been published by Georg Thieme, Leipzig. We noticed the third edition in March of last year (vol. xlix. p. 455), and the present issue sustains the commendation then given, viz. that "the volume is undoubtedly one of the best introductions to the study of bacteriology which has yet been produced." Another new edition which we welcome is the "Cours Elementaire de Manipulations de Physique," by Prof. A. Witz, published by Gauthier-Villars. The book contains a descriptive course of work covering the fundamental principles and laws of physical science. Each experiment is divided up into four sections, as follows: first, the theory of the experiment is stated; then the apparatus is described; the experimental operations form the subject of another section, and the results of observations are given in the fourth. Though the book is here and there deficient in the details required by students of practical physics, it is altogether a useful companion to the physical laboratory.

THE Catalogue of the Library of the Royal Geographical Society, compiled by Dr. H. R. Mill, and lately published, is a very full and valuable index to the literature of geography. The Catalogue contains the titles of all works in the possession of the Royal Geographical Society published up to the close of 1893. The entries (amounting to as many as 18,000) are arranged in four divisions. The first division, which runs into 521 of the 833 pages, is a general alphabetical author's catalogue; the second comprises collections of voyages and travels, arranged in alphabetical order under authors' names, and containing a brief analysis of the contents of each volume; in the third division, Government, anonymous, and other miscellaneous publications are arranged geographically; while the fourth consists of a list of transactions and periodical publications, arranged in a similar manner according to the place of publication. With such a comprehensive classification, it is easy to find the works of each author, and to refer to the literature concerning different divisions of the earth. A valuable supplement to the Catalogue will be the subject index now being prepared, and in which the principal contents of all the geographical books and periodicals belonging to the Society will be classified.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by the Rev. Sidney Vatcher; a Crested Porcupine (*Hystrix cristata*) from East Africa, presented by Captain B. L. Sclater; three Common Rheas (*Rhea americana*) from South America, presented by Mr. Robert Gunther; four Rhomb-marked Snakes (*Psammophylax rhombeatus*), three Crossed Snakes (*Psammophis crucifer*), two Rough-keeled Snakes (*Dasypeltis scabra*), a Smooth-bellied Snake (*Homalosoma lutrix*), a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by Mr. J. E. Matcham; a Bonnet Monkey (*Macacus sinicus*) from India, a Yellow Baboon (*Cynocephalus babouin*) from West Africa, a Rose Hill Parrakeet, (*Platycercus eximius*) from Australia, deposited; three Prevost's Squirrels (*Sciurus prevosti*) from Malacca, purchased.

OUR ASTRONOMICAL COLUMN.

THE OBSERVATORY ON MONT BLANC.—Two causes combined to induce Dr. Janssen to undertake his recent ascent of Mont Blanc. First, he was anxious to be convinced of the perfect safety of the new telescope which has been conveyed to the observatory; and second, the meteorograph had ceased to perform its various important duties (*Comptes rendus*, October 7). It is intended to mount the telescope, which has an aperture of thirteen inches, with its axis parallel to that of the earth, and a mirror nearly twenty-four inches in diameter will be employed to reflect the light of the heavenly bodies into the telescope; the mirror and telescope will have a common movement, so that the relative positions of the stars will not change on account of the diurnal motion. The meteorograph was found to be some-

what unstable, but arrangements have been made by which it is hoped that the records may be continued. A slight movement of the observatory towards Chamounix was noted, but it is expected that future displacements will be insignificant; and, in any case, the means are at hand to restore it to its original position. The practicability of the establishment of observatories on snow-clad mountains is therefore no longer to be questioned, and the multiplication of such institutions as that on Mont Blanc will no doubt contribute largely to our knowledge both in meteorology and astronomy.

It is characteristic of Dr. Janssen that he should take advantage of the opportunity of observing the aqueous bands in the solar spectrum. The air above him being very rare and also extremely dry, he found that when observing sunlight in its totality the bands at C and D were absolutely invisible, while the group at α was so pale that its presence could scarcely be determined. Dr. Janssen already regards it as certain that there is neither oxygen nor aqueous vapour in the solar envelopes, but the question is so important that too many observations cannot be made. To carry the observations a step further, it will be necessary, under analogous atmospheric conditions, to compare very carefully the centre of the sun's disc with the edge, to see if there is any augmentation of the α group as the limb is approached, this group being especially sensitive to variations in the amount of absorbing vapour.

EPHEMERIS FOR FAYE'S COMET.—The following ephemeris, for Berlin midnight, is given by F. Engström in *Astr. Nach.* No. 3313:

	R. A. h. m. s.	Decl. ° ′
Oct. 17	21 11 9	−4 20·6
19	12 10	31·7
21	13 18	42·1
23	14 32	51·0
25	15 54	5 1·0
27	17 23	9·5
29	18 59	17·3
31	20 42	24·5
Nov. 2	22 32	31·0
4	24 28	36·7
6	26 30	41·6
8	28 38	45·8
10	30 52	49·3
12	33 13	52·2
14	21 35 39	−5 54·4

The calculated brightness is practically constant throughout the above period. Perihelion passage will not occur until March 19, 1896.

VISIBILITY OF THE DARK SIDE OF VENUS.—Various theories have been advanced at different times to account for the visibility of the hemisphere of Venus which is not illuminated by the sun, but there is no general agreement as to which is the most probable. Still another explanation is offered by M. Camille Flammarion, and it has the merit of being based on careful observations made at Juvisy during August and September of the present year (*Bull. Soc. Ast. de France*, October). The planet was frequently observed in full sunshine by M. Flammarion and his assistants, and the observations appear to put the matter in quite a new light. To these observers it has several times seemed that the interior of the crescent of Venus was darker than the sky, even on the day of inferior conjunction. That this appearance was not simply an effect of contrast produced by the luminous crescent is shown by the fact that no such darkening was apparent at the exterior edge of the crescent, and again by the visibility of the obscure hemisphere when the luminous part was artificially eclipsed. The colour of the unilluminated area was slightly violet in all the varied conditions of observation. M. Flammarion considers that the observations can be best accounted for by supposing that Venus is projected on a somewhat lighter background, such as might be furnished by the zodiacal light, or an extended solar atmosphere. The violet tint which was noted may have been due to the considerable refraction of the sun's rays by the atmosphere of the planet, the reddish tinge thus produced on the planet appearing purple when seen through our own blue sky.

In the same article, M. Flammarion gives some interesting facts relating to the history of the phenomenon, and some calculations which indicate that "earth-shine" is insufficient to account for it. Under the most favourable conditions, the terrestrial light received by Venus is 12,000 times feebler than that received by the moon, and 822 times less intense than the light we receive from the full moon.

THE MELBOURNE OBSERVATORY.—The twenty-ninth report of the Government Astronomer, Mr. R. L. J. Ellery, on the work of the Melbourne Observatory during the year ending at the beginning of last June, has just come to hand. Meridian observations, the daily photography of the sun, magnetic and meteorological observations, have been carried on as heretofore. The number of plates secured, in connection with the photographic chart and catalogue, up to June 1, was 1080. Preliminary measures have been made of 238 plates to obtain the positions where possible, of five stars on each plate, to be used for the determination of the constants of the plates. Mr. Ellery refers to the important change in time-reckoning made in February last by the introduction of zone or standard time in all the Australian colonies. By the zone system, Eastern Australian time, which covers Queensland, New South Wales, Victoria, and Tasmania, conforms to that of the 150th meridian; and this makes Melbourne exactly ten hours in advance of Greenwich time, instead of 9h. 30m. 54s., which is the true difference of longitude. The retirement of Mr. Ellery from his post as Government Astronomer has already been noted in these columns. Mr. Ellery has built up the Melbourne Observatory from its very small beginning in 1853 to its present recognised position among the national observatories of the world; and we are glad to see that the Government has appointed him a member of the Board of Visitors, so that he has not entirely severed his connection with the observatory. He has been succeeded in the directorship by the chief assistant, Mr. P. Baracchi, whose pendulum observations are well known to students of terrestrial physics.

A NEW OBSERVATORY.—The New York *Nation* notes a new departure at the University of Pennsylvania, by the addition of an astronomical observatory. The observatory has already been commenced, and, when completed, it is designed to furnish better facilities, not only for instruction, but for original research as well. The new edifice is two miles from the limits of Philadelphia, and about five miles from the university buildings. The instruments are an eighteen-inch equatorial, with spectroscope attachment, by Brashear, and a meridian circle and zenith telescope, each of four inches aperture, also by Brashear. The mountings are by Warner and Swasey. This institution will be known as the Flower Observatory, and its director is Prof. C. L. Doolittle, formerly of the Lehigh University.

THE INTERNATIONAL CONGRESS OF PHYSIOLOGISTS AT BERN.[1]

II.

THURSDAY morning, September 12.—Presidents: Profs. Dastre and Wedensky. Prof. Arloing (Lyons) gave the result of his researches on the persistence of electric irritability in the peripheral ends of divided nerves. The author found that the length of time for which electric irritability was retained varied with the species of animal, and also with the individual, and further that it was different both for different nerves and for the different kinds of fibres in compound nerves, such as the vagus. For spinal nerves the irritability lasted from four to five days in dogs, and from eight to ten days in horses. In one ass the author obtained cardiac inhibition with a rise of blood pressure, upon stimulating the peripheral end of the vagus fifty-seven days after section: this result he attributed to a tetanus of the myocardium.

Dr. Arthus (Paris) defended the view that the salts of calcium are necessary to the coagulation of the blood, against that of Alex. Schmidt, who does not believe their *rôle* to be an essential one. He further discussed the action of neutral solutions of the oxalates, fluorides, &c., in rendering the blood incoagulable. He disagreed with Schmidt, who holds that they act specifically, and maintained that their effect is due solely to the fact that they precipitate the calcium salts. Arthus repeated Schmidt's experiments, and was unable to confirm his results.

Prof. v. Kries (Freiburg) discussed the phenomena of colour vision in eyes adapted for darkness.

Prof. Gamgee (Lausanne) gave the result of his researches on the violet and ultra-violet spectrum of hæmoglobin and its derivatives. He exhibited photographs which showed the

[1] Continued from p. 580.

[illegible] in the spectra of [illegible] of CO and NO [illegible], which band was shown to be displaced towards the less [illegible] end of the spectrum. This very remarkable [illegible] he showed to be due to the hæmatin [illegible] of the [illegible] molecule, and to be independent of the [illegible]. Prof. [illegible] described and showed photographs of the spectrum of [illegible], a pigment obtained from the feathers of certain birds. This substance, containing 6·0 per cent. of copper, gives a spectrum identical with that of hæmoglobin. A demonstration [illegible] at which the spectra were shown.

Prof. Burdon Sanderson (Oxford) gave a demonstration, illustrated by slides, of electrometric photographic curves, and [illegible] the following propositions.

Proposition A.—There are two kinds of electrical response [illegible] excitation of a muscle by its nerve. I. Diminution of the E.M.F. of the previously existing [illegible] current. II. The excitation wave. The first (I.) is evoked when the nerve is stimulated by equal alternating currents of great frequency, (b) by the constant current, (c) by salt crystals, &c. The second (II.) [illegible] in uninjured muscle (a) by single electrical and [illegible] momentary excitations, (b) by rhythmically repeated momentary excitations (true tetanus). I. and II. exist together in rhythmical excitation of injured muscle.

Proposition B.—In the reflex spasm of strychnine each phase of excitation resembles I. The strychnine spasm is no true tetanus.

Dr. Waller (London), gave the results of his researches on the influence of chemical reagents on the electrical excitability of isolated nerve. Excised frogs' nerves were rhythmically excited once a minute during one-eighth of a minute. The current of action was recorded by a galvanograph. The nerve was enclosed in a gas chamber to study the effects of gases, and dipped for one minute in decimolecular solutions for salts, and 1 per cent. solutions for alkaloids. By means of this method Dr. Waller was enabled to study the action of a large number of bodies, the results of which he gave; his researches also extended to the study of physiological antagonism.

Dr. Epstein (Bern) showed that the increase in the acuteness of vision, which occurs under the influence of auditory impressions, can be experimentally demonstrated. The author described the apparatus. He further expressed the opinion that the centre for this process lay not in the cortex, but in the superior corpora quadrigemina. He regarded it as essentially dependent upon [illegible] reflex sensibility of the retina, the optic nerve containing the efferent fibres; in favour of this view, he quoted an experiment in which by faradic excitation of the nerve from the cochlea he obtained eye movements, and increased conjunctival reflex.

Tuesday Afternoon.—Presidents, Profs. Nitzau and Fredericque. Prof. Rutherford (Edinburgh) gave an account of his researches on the structure and contraction of striped muscular fibre. His observations were mostly made upon crabs' muscles fixed in a 4 per cent. solution of formaldehyde, and then stained with [illegible] or [illegible]. He regards the fibrils as the essential elements of the sarcous substance, each fibril has in its whole length a [illegible]. He regards the fibril as composed of a series of segments: (1) Bowman's element, (2) the intermediate segment placed midway between successive Bowman's elements, and (3) the clear segment placed between (1) and (2). The intermediate segment is tripartite, and consists of Dobie's [illegible], forming a node in its equator, and Flogel's element N [illegible] on each side of it. During contraction, the [illegible] consists in the shortening of the interval between [illegible] ends of Bowman's elements. This stage of the contraction probably results from the absorption of fluid by [illegible]. In the next stage Bowman's elements [illegible] real contraction of their tissue, [illegible] to their ends, which become swollen.

[illegible] gave the results of their researches [illegible] of the posterior roots of the spinal nerves from the [illegible] to the second dorsal. [illegible]

[illegible] read a paper on [illegible]. The author [illegible]

[illegible] showed an apparatus for the [illegible]

[illegible] read a paper on the

fibre in fever. In fever the red blood-cells are diminished; tepid baths but not antipyretics bring the number again to the normal. In artificial fever (rabbits raised to a temperature of 50° C.) the red blood-cells are also greatly diminished in the systemic veins, but are increased in the liver.

Dr. Gley (Paris) discussed the action of the intra-vascular injection of solutions of peptones in rendering the blood incoagulable. He showed that these bodies did not possess this action after the ligature of the lymphatics coming from the liver. From this experiment the author inferred that the substance which renders the blood incoagulable, and is produced in the organism under the influence of the peptones, is secreted by the hepatic cells.

Dr. I. V. Uxhill (Heidelberg) showed an apparatus for the rapid mechanical stimulation of the nerve of a muscle-nerve preparation.

Dr. Schenk (Würzburg) read a paper on the innervation of the iris. The author's communication chiefly concerned the observation of Dogel, that upon stimulation of the cervical sympathetic in cats, dogs and rabbits, in addition to the dilatation of the pupil on the same side, a contraction of the pupil on the other side occurred. Schenk regarded this phenomenon as a consensual pupil reflex (consensuelle Pupilla Reflex). In Dogel's experiments the eye on the same side as the stimulated sympathetic was exposed to the light; hence during stimulation more light entered the pupil, and this caused contraction of the pupil of the opposite side. When the eye on the stimulated side was shaded from the light, the contraction of the other pupil did not take place. This explanation would not hold for rabbits, as in them the consensual pupil reflex is absent; the author was, however, in the case of rabbits, unable to repeat Dogel's results.

Dr. Leathes (London) read a paper on the osmotic changes between the blood and the tissues. The author gave the result of his experiments on the influence of strong solutions of cane-sugar and dextrose, and of iso-, hypo-, and hyper-tonic solutions of NaCl in causing the passage of fluid from the blood into the tissues, or *vice versâ*. The author further discussed the osmotic pressure of the lymph in the thoracic duct, which he found $\frac{1}{100}$ to $\frac{1}{50}$ higher than that of the blood.

Friday Morning, September 13.—Presidents, Profs. Rosenthal and Langley. Prof. Wedensky (St. Petersburg) read a paper on the exciting and inhibitory action of electric tetanisation on the nerve-muscle apparatus. The author showed that, if induced currents of great frequency and intensity be applied to the sciatic nerve, the gastrocnemius contracts strongly but soon relaxes; if at this time the intensity of the exciting currents be diminished until they become moderate, a very strong (optimum) contraction of the muscle takes place. Further, if when the muscle is in a condition of relaxation produced by the application of strong and frequent induced currents to the nerve, one diminishes the frequency, a strong tetanic contraction can be reproduced, which at once disappears upon again increasing the frequency. There is for each stage of tetanisation an optimum of frequency. The relaxation of a muscle, under the application of strong and frequent induced currents to its nerve, is caused by the nerve-endings entering into a condition of inhibition. This can be demonstrated by applying to the muscle moderately strong induced currents; no effect is produced until the strong and frequent tetanisation of the nerve is discontinued.

Dr. Luscher (Bern) read a paper on the nervous mechanism of swallowing. The author's experiments were made upon rabbits. He showed that the three branches of the recurrent laryngeal overlapped in their distribution to the œsophagus, *i.e.* each branch supplied some of the region supplied by the other. After division of the recurrent laryngeal stimulation of the central end of the superior laryngeal did not produce swallowing. Upon stimulation of the central end of the divided recurrent laryngeal (the nerve of the other side being intact) a faint act of swallowing was produced. Stimulation of the central end of the vagus only gave rise to swallowing when the recurrent laryngeal was intact.

Prof. Bowditch (Boston) showed an apparatus to demonstrate the mechanism of the ankle-joint. By the introduction of a spring balance into the cord representing the gastrocnemius muscle, and the application of a weight, he could determine the relation between power and weight for the action of this muscle.

Dr. Waller (London) read a paper on the photo-electric [illegible] of the retina.

Prof. Hensen (Kiel) gave a demonstration on an acoustic apparatus, the result of which was to show that the view of Helmholtz, that the vowels owe their special quality to overtones produced in the mouth and adjoining cavities, requires modification: this, in the author's opinion, is impossible.

Friday Afternoon.—Presidents, Profs. Richet and Cybulsky. Dr. Sherrington (London) gave a demonstration on eye movements.

Dr. Lanz (Bern) read a paper on the effect of removal of the thyroid, and of thyroid-feeding in normal animals. Among many interesting results, the author found that thyroidectomised hens either lost their power of laying eggs, or laid very small and ill-formed ones. On the other hand, hens fed with thyroids (30 grms. per diem) had their egg-laying power greatly increased. In some animals the author found that the administration of large quantities of thyroid gland caused an arrest of growth.

Dr. Phisalix (Paris) showed that the blood of the salamander rendered animals immune to curare. This immunity in the case of the frog and pigeon lasts several days.

Prof. Mosso (Turin) read a paper on the effect of rarefied air upon man and apes. The author's researches on man were made on Mount Rosa, at a height of 5000 metres. The author showed that at this altitude the respiratory exchange is diminished; his observations were made under conditions of absolute rest, mostly during sleep. In the explanation of these phenomena the author thinks more attention should be paid to the diminution of CO_2. He describes them under the name of Akapnia (καπνος = smoke). Mosso further described an experiment which he made upon a monkey. He subjected this animal to an atmosphere of pure O at a low pressure; he observed under these conditions the phenomena of mountain-sickness (*Bergkrankheit*) even when the pressure of the O exceeded the partial pressure of this gas in the atmosphere under ordinary circumstances. The author concluded that the two main factors which come into play at high altitudes are (1) the diminution of CO_2 in arterial blood; (2) the physical effect of low pressure on the nervous system.

F. W. Tunnicliffe.

CORRESPONDING SOCIETIES OF THE BRITISH ASSOCIATION.

The first meeting of the Conference took place on Thursday, September 12, the second on Tuesday, September 17, at the Co-operative Hall, at 3.30 p.m.

At the first meeting, the Corresponding Societies Committee was represented by Mr. G. J. Symons (Chairman), Prof. R. Meldola, Mr. J. Hopkinson and Mr. T. V. Holmes (Secretary). The Chairman opened the proceedings with an address.

On the conclusion of the address, Mr. T. V. Holmes made a few remarks with regard to the list of papers read before the various Corresponding Societies, and appended to the Report of the Corresponding Societies Committee. He hoped that the Secretaries of the Corresponding Societies, in preparing their lists, would be careful to group papers, which from their titles might belong to either of two Sections, with that to which they had most affinity. It was also most desirable that the names of papers sent in should not turn out to be mere popular lectures, but should contain something original. It had sometimes happened that on wishing to refer to some paper on the list sent in by some Society, in order to ascertain its true character, it could not be found on their shelves at Burlington House. In future no paper could be placed on the list published by the British Association unless it was on their book-shelves.

Captain Elwes (Dorset) laid upon the table a paper on the rainfall in the county of Dorset, which had been compiled by a member of the Dorset Natural History and Antiquarian Field Club, Mr. Eaton. It was a most careful piece of work, and was illustrated by maps and diagrams.

Mr. Hopkinson said that about twenty years ago he began to note the rainfall of Hertfordshire with about twenty observers. Last year the record he published contained the monthly returns from forty observers. He trusted that delegates would preserve any early meteorological records they might find.

Mr. De Rance remarked that the increasing usefulness of local societies was shown by the fact that two British Association Committees had ceased to exist, that on coast erosion, and that on the circulation of underground waters, on account of the admirable way in which their work had been taken up by the local societies.

His Honour Deemster Gill said that the subject of coast erosion had been taken up by a Committee of the Legislature of the Isle of Man, but their investigations were not yet complete. They had found that for some twenty miles on the west, the north-west and the north, there had been a destruction of land of about twenty acres to the mile within the last fifty or sixty years. The meteorology of the Isle of Man was also being well looked after.

Mr. Sowerbutts asked whether it was desirable that the Manchester Geographical Society should collect the results of observations at their local observatories, and forward them to the Meteorological Society; and the Chairman replied in the affirmative.

Capt. Elwes hoped that local societies might be induced to co-operate for the discovery of flint implements, and the formulation of the results attained.

Mr. Osmund W. Jeffs, Secretary to the British Association Committee for the collection and Preservation of geological Photographs, said that the photographs collected would be placed in the Museum of Practical Geology, Jermyn Street, London. The first part of the collection, 800 photographs, had already been placed there. It was proposed to go on collecting, as many parts of the British Isles were quite unrepresented.

Mr. De Rance thought that it would be a good thing if each society would issue a circular and send it to other local societies, so that it might be known what photographs had been taken in each locality.

Mr. J. B. Murdoch (Glasgow) thought that in too many of their investigations Scotland was excluded. He mentioned, as an instance, the British Association Committee for recording the position, &c., of erratic blocks of England, Wales and Ireland.

Some discussion arose on this point, in which Mr. De Rance, Mr. Sowerbutts and Mr. G. P. Hughes took part. Then the Chairman said that he believed Scotland had been omitted in that instance because the Royal Society of Edinburgh had been working at the subject before the formation of the British Association Committee.

Mr. Murdoch replied that it was true that a Boulder Committee had existed in Scotland, but its director, Mr. Milne Holme, was dead, and had been unable to get about the country for some time before his death. The eight yearly reports issued by his Committee were very valuable, but for some time the work had been practically at a standstill.

The Chairman remarked that in that case it was most desirable that Scotland should be included by the Erratic Blocks Committee.

Deemster Gill said that the boulders of the Isle of Man were being noted by the Isle of Man Natural History and Antiquarian Society.

Prof. Meldola moved, and Mr. Hopkinson seconded, a motion in favour of an application to the General Committee for a grant of £30 to enable the Corresponding Societies Committee to carry on its work. This was carried, and the meeting ended.

At the second meeting, on Tuesday, September 17, the Corresponding Societies Committee was represented by Dr. Garson (in the chair), Mr. Hopkinson, Mr. Symons, and Mr. T. V. Holmes (Secretary).

The Chairman said that it was usual at their second meeting to consider the recommendations from the various Sections respecting work in which it was thought the Corresponding Societies might usefully co-operate.

Section A.

Mr. White Wallis, representing Section A, said that the Committees for investigating earth tremors and seismological phenomena in Japan had been merged into one, with the title of "Committee for Seismological Observations." The Committee for the application of photography to meteorology had been reappointed, and so had the Underground Temperature Committee. The Meteorological Photographs Committee was simply desirous to obtain photographs of lightning, rainbows, halos, &c.

The Rev. J. O. Bevan inquired whether the meteorological work formerly carried on at Stonyhurst by Father Perry was still going on. Mr. Sowerbutts answered that it was, and Mr. White Wallis said that he would note the suggestion that they should communicate with Stonyhurst. He added, in answer to questions, that instruments for noting earth tremors were unaffected by vibrations from passing waggons, trains, &c.

Section C.

Mr. A. S. Reid, representing Section C, stated that Mr. Osmund Jeffs had consented to retain the post of secretary to the Geological Photographs Committee for another year, as Mr. W. W. Watts had agreed to act as co-secretary during that time, and afterwards to become sole secretary. The Erratic Blocks Committee had altered its title so as to include Scotland.

Mr. Murdoch hoped that the Earth Tremors Committee might include Scotland in its sphere of action. It was then a purely English Committee.

Mr. M. B. Slater thought that an exchange of local geological photographs among the various Corresponding Societies would be a good thing. Some discussion then took place on the practical difficulties likely to arise from an interchange, such as the burden likely to be laid upon the shoulders of the amateur photographer, &c. Mr. Hopkinson thought that copies should be obtainable at the Jermyn-street Museum at a small fixed charge, and Mr. Reid mentioned a plan suggested by Mr. Gray of Belfast. At that town a photographer had been appointed who received the negatives taken by various members of the local societies, and furnished as many copies as were required at a small fixed charge.

Section E.

Mr. Sowerbutts said that the Committee of Section E had asked the Council of the British Association to permit them to have a Committee for the purpose of making an inquiry into the condition of the teaching of geography in Great Britain in all schools, especially secondary schools, and to report next year. It was probable that the Corresponding Societies might be asked to furnish certain information, and he hoped their secretaries would reply as promptly as possible.

The Rev. J. O. Bevan thought that the statements made in the report of the Conference of Delegates at Nottingham, that in some county, unnamed, "children attending schools were not taught geography in any way," and that geography was absolutely ignored in secondary schools, were decidedly erroneous, though in some primary schools it was not taught except in connection with reading. The Royal Geographical Society had instituted examinations in geography in secondary schools, and gave gold medals and other prizes.

Section H.

Mr. Hartland said that he was there owing to the very sad bereavement sustained recently by Mr. Brabrook, the Chairman of the Ethnographical Survey Committee, who was consequently unable to attend. The Ethnographical Survey was a matter in which the Corresponding Societies were especially capable of rendering valuable assistance. They had hitherto, however, met with but little response from the local societies. The work had so many branches that some of them could scarcely fail to interest their more active members. If the Committee obtained the grant for which they asked, they proposed to begin work in Galway, and he hoped to report progress at the next meeting. He would be glad if meanwhile the Corresponding Societies would circulate their schedules, and bring the Survey under the notice of their members.

Mr. M. B. Slater mentioned the work done in the neighbourhood of Malton by a sub-committee, of which Dr. Colby was chairman; and Mr. Hartland remarked that the Malton Naturalists' Society was one of those which had responded to their circular.

The Chairman noted the great variety of the work of the Ethnographical Survey, which included questions of physical characteristics, folk-lore, linguistic differences, place-names, traditions, &c. Satisfactory work had been done around Ipswich.

Mr. Hartland wished also to mention the preservation of ancient monuments. He had just received a letter from the Secretary of a local committee in Pembrokeshire, mentioning the recent discovery there of some ancient stones and some pit dwellings.

Mr. Hopkinson thought that the measurements asked for were very elaborate, and the questions were considered inquisitorial. He was sure that a simpler system would be found to answer better in practice, as then more societies or persons would be found willing to undertake the work.

Mr. Hartland hoped that members who objected to the [illegible] would take up the subjects of dialect, folk-lore, or prehistoric monuments. Though they hoped to be able to secure the elaborate measurements in some cases, they were glad to get such measurements as could be procured. They did not consider their standard as of universal obligation.

The Chairman wished to say a few words about another Committee, that concerned with the measurement of school children. Many schools had been doing good work in this way, but unfortunately there had been no uniform system, so that the results obtained at one school could not be compared with those at another. The Committee had drawn up a system which he hoped would prove acceptable to the various schools.

Dr. Brett (Hertfordshire) said that since the York meeting of the British Association, fifteen years ago, it had been his custom as a medical man to record the height, weight, colour of hair and eyes, &c., of children. He had up to that time made about three thousand observations, but had not yet been able to put his records into shape.

The Rev. J. O. Bevan spoke of the desirability of expediting the archæological survey of the kingdom, which had been begun a few years ago. He was then at work at the map of Herefordshire, which was nearly ready for publication. He was surprised that the work had not been taken up more energetically by properly qualified persons in the different districts.

THE AFFILIATED SOCIETIES OF THE AMERICAN ASSOCIATION.

A FEATURE of the meetings of the American Association for the Advancement of Science is the number of affiliated societies which meet at nearly the same time and place, though having no organic connection with it. One disadvantage of this is that the Sections of the Association do not get many of the important papers read before the affiliated societies; in fact, these societies seem almost to take the place of the Sections, and they certainly tend to put the Association in a secondary position. As a large number of the papers were more of local than of general interest, we confine ourselves to a brief statement of the societies which met at Springfield during the recent meeting of the American Association, and of a few of the subjects considered.

The Society for the Promotion of Agricultural Science discussed several papers on spraying as a prevention of the attacks of various insect pests and fungi, and also on cereal culture in the United States. At the end of the proceedings, Mr. R. Lazenby was elected President of the Society.

The attention of the Association of Economic Entomologists was largely directed to the results of experimenting with insecticides, and the methods of placing the knowledge before all agriculturists. A resolution was passed asking the Massachusetts authorities to support the work of the Gipsy Moth Commission. Another resolution was adopted asking that the publication of "Insect Life" by the Department of Agriculture be resumed. The officers for the ensuing year are: President, Prof. C. H. Fernald; first vice-president, Prof. F. M. Webster; second, Prof. Herbert O. Ames; secretary, C. L. Marlatt.

The session of the American Forestry Association was a very successful one. In the course of a short communication, Baron Herman pointed out that Germany has comparatively the most forests in well-regulated administration of all the countries of the world; that is, one-fourth of its whole area is covered with them (all under long and careful management). There is scarcely one tree in the whole of the fatherland which is not known personally to a forest officer, and which has not been sown or planted with more or less great care and labour. The whole area of wooded land is almost equally divided between State, community, and private persons. And it is thought that this is a very good state of affairs, the commonwealth being in that way well interested in its parts as well as in the whole, in the affairs connected with the forest growth. This of course influences legislation, and although laws concerning the forests are not passed in the Reichstag, but in the Parliaments of the individual States, there is scarcely a part of Germany where one is allowed to cut down a forest, and not plant it again, without the permission of the Department of Forestry. The forests are managed by hundreds of forest officers, and these are educated at special colleges for forestry, there being no less than eleven in Germany. The theoretical study at these colleges lasts generally four years, not counting the time a young man has to spend in learning practical work in the woods. This comparatively long time a man wants, for his training shows how very much the science of forestry has been developed in

its different branches in Germany. After a man has passed his examinations he may often have to wait for years and years before he gets an appointment; but the love of the woods, the poetry which time has woven around the solitary *forsthaus* amidst the trees and animals of the woods is so great they do not mind waiting a long time. In conclusion, Baron Herman said he was in America to see what trees could be transplanted with success to Germany.

After a paper on the present condition of the forests of America, the following resolutions were adopted, among others:—

"That the American Forestry Association join with the New York Chamber of Commerce and Board of Trade in hearty advocacy of the establishment of a forestry commission of three members to make a thorough investigation of the public forest lands, and to make recommendations concerning their disposition and treatment, and the executive committee is hereby directed to represent the Association in support of such legislation."

"That the American Forestry Association recognising that a practical advance in rational forestry methods requires the services of men trained in forestry practice, endorse the legislation proposed in the last congress, and expresses the hope that the same will be enacted during the coming congress."

"That the knowledge and extent and conditions of our forest resources is a necessary basis for intelligent forest legislation, and that therefore the American Forestry Association recommends the co-operation of various government departments as far as practicable in ascertaining their areas and conditions, and especially recommends that both a topographical and forestal survey of the national forest reservations be instituted."

Sixteen papers were read before the American Mathematical Society, and two topics were discussed, viz. (1) a general subject catalogue or index of mathematical literature, and (2) the mathematical curricula of colleges and science schools. With reference to the former subject, it was resolved that the Council of the Society consider the desirability of offering their co-operation to the Mathematical Society of France in the work of classifying and indexing mathematical literature.

The American Chemical Society was presided over by Prof. E. F. Smith; and among the subjects of papers read before it were: an electrical process for the production of white lead; the heating effects of coal; speed of oxidation of chloric acid; reaction between copper and concentrated sulphuric acid; use of aluminium for condensers in the distillation of alcohol, ether, chloroform, benzine and similar liquids. Prof. Norton, who read the last-named paper, stated that the equipment of the chemical laboratory of the University of Cincinnati includes aluminium supports, rings, clamps, burners, water-baths, air-baths, hot water funnels, &c., in all of which connections the lightness, conductivity, and freedom from rust render the metal superior to iron or bronze.

The Botanical Society of America, which was organised in Brooklyn last year, held its first annual meeting on August 27 and 28. Mr. William Trelease presided. The officers elected for the ensuing year are: President, C. E. Bessey; vice-president, W. P. Wilson; secretary, Charles R. Bainer; treasurer, Arthur Hollick.

Prof. G. F. Swain opened the proceedings of the Society for the Promotion of Engineering Education with an address on the relation between mental training and practical work in engineering education. The papers read before the Society, and the discussions to which they gave rise, will do much to indicate what should be the scope of engineering and technical schools, and the places of different subjects in an engineering education. The units of force best adapted for use in the teaching of mathematics formed the subject of a discussion between the physicists and engineers. At the end of the meeting, Mr. Mansfield Merriman was elected President.

ON RECENTLY DISCOVERED REMAINS OF THE ABORIGINAL INHABITANTS OF JAMAICA.[1]

THE circumstances under which the human remains now exhibited to the meeting were discovered, are narrated in a communication by Mr. F. Cundall, Secretary to the Jamaica Institute, published in the *Journal* of the Institute for April 1895, and also in a letter by Mr J. E. Duerden, Curator of the Museum, in NATURE of June 20. From the former I extract the following description of the discovery:—"On the 10th April, a labourer, whilst cutting stakes on the Halberstadt Estate (a wild, rocky part of the Port Royal Mountains, about 2000 feet above the sea-level, and two miles from the shore) on the estate of Mr. B. S. Gossett, a quarter of a mile east of the Kalorama Mission Station, discovered on the hillside a human bone. This led the Rev. W. W. Rumsey to make a search on the following day, when he discovered a small aperture 25 inches wide, and less than 2 feet high, in the face of the limestone rock, and blocked by boulders; on removing these, and passing through which, he discovered a cavern with water-worn sides, partially covered with stalactite deposits, penetrating into the rock for a distance of about 20 feet, about 5 feet across at its widest part, and not more than 2 or 3 feet high. The floor was covered with a deposit about 12 inches thick, of a fine light yellowish dust, but the remains were superficial."

In addition to the human bones, to be presently described, were found a considerable portion of a cedar-wood canoe, about 7 feet long, fragments of pottery, including two, nearly perfect, earthenware vessels similar to those known to have been made by the Arawak Indians, an outer portion of the trunk of an *arbor-vitæ*, probably serving at one time as a "mortar," scarcely showing any sign of decay; the perfect skulls and other parts of the skeleton of a rodent (the so-called Jamaica coney, *Capromys brachyurus*); two large marine shells (*Fusus* and *Murex*), the soft parts of which are still eaten by the natives, numerous land shells (*Helix*, &c.). A flint implement is also mentioned in Mr. Duerden's account.

The only portion of the contents of the cavern submitted to me for examination consist of the human bones, and as they only arrived in London a few days before I was leaving town, at present I have only been able to make a general examination of them, without any detailed measurements.

Their principal interest consists in the circumstance, proved both by the conditions under which they were found, and by their own characteristics, that they are the remains of the race which inhabited the island previous to its discovery by the Spaniards, by whom they were in so short a time barbarously and utterly exterminated.

Whatever condition the bones were found in as they lay in the cave, they are now completely mixed up, and it is impossible to put together anything like complete skeletons, or even, except in very few cases, to associate the bones of individuals; and the number of odd bones and fragments show that large portions of the individuals who were buried or died in the cave are now missing. Their general condition of preservation, colour, &c., is nearly the same in all, so there is no reason to suppose that they were not contemporaneous. None of the bones show any wounds or marks of violence, but all appear to be those of persons who have died a natural or slow death. Both sexes and almost all ages are represented, from children of four or five years to very old persons, the proportion of the latter, as will be seen, being remarkable.

Of the crania, there are six complete, all those of fully adult or aged persons, and two calvariæ (without the facial portion), both of children. There are also fragments of six others, giving evidence of fourteen individuals.

Of the adult skulls three appear to be masculine and three feminine in type.

Five of these show evidence of artificial depression of the frontal region in various degrees. In two it is very marked; in the others less so. In the sixth, though the frontal region is low, no effects of artificial deformation are evident. Both the children's skulls are very broad and flat, but whether naturally so, or whether this character has been exaggerated artificially it is difficult to say. The mode of depression, when it occurs, is similar in all, evidently produced by the flat board upon the forehead the commonest custom throughout so large a portion of the ancient inhabitants of the American continent.

Although there is a considerable general resemblance between these skulls, they present strong individual characters; but their whole aspect, taken together, is characteristic of the American type. The retreating forehead, well marked supraciliary ridges, round broad arch of the palate, round high orbits, narrow nasal aperture, and especially the narrow prominent nasal bones, causing a high bridge to the nose during life, are very characteristic. There are, however, two rather remarkable exceptions to this form of nose, in which the breadth of the aperture and flatness of the

[1] Read before Section H of the British Association at Ipswich, September 12, by Sir William H. Flower, K.C.B., F.R.S.

[illegible] almost equal those of the negro; the nasal index being as high, respectively, as 542 and 563. These are both feminine-looking heads, and one of them is the most and the other the least deformed of the set. Whether this form of nose is met with in any other undoubtedly aboriginal American crania, is subject for investigation. Apart from these, the skulls are remarkably like the majority of those which I have seen of Peruvians, Mexicans, and the ancient mound-builders of the United States.

Of lower jaws there are in all twenty-two, a number which indicates that many of the crania must now be missing from the collection. They are interesting as showing age, and peculiarities of dentition; nineteen are adults, and three young. The youngest has the milk teeth only—the first permanent molar, and first incisors being just about to appear (about six years old). One is a little older, the first molar being fully in place with the two milk molars. Another has all the permanent teeth in place, except the last molars (wisdom teeth), which are still in their alveoli.

In all the others the permanent teeth appear to have been fully in place, but the number of losses sustained during life is remarkable. As so many of the teeth have dropped out since death, it is mainly by the condition of the alveoli that their presence or absence during life can be judged of, for in only two or three do all appear to have been retained. Two are absolutely edentulous. In eight, not one of the true molars remain, the whole available dentition being represented by the incisors, and in a few cases by an isolated canine or premolar. Seven had lost one or more of the true molars. All the teeth, except those of the very young individuals, are much worn, but scarcely any show signs of disease or decay, there being only three small carious cavities among them all. Yet the milk molars in both the child's jaws, which were soon to be shed, have their crowns deeply excavated.

The only dental anomaly is that in one of the skulls the right upper wisdom tooth is placed horizontally, its crown projecting outwards through the surface of the maxillary bone its lower edge two millimetres above the alveolar border.

The limb bones indicate an average height rather below the middle size, but, as just stated, I have not yet had time to make accurate measurements and calculations.

Clavicle, 7 right, 10 left, all adult. *Scapulæ*, all more or less broken; fragments of 15 right and 11 left adult, and 1 young. *Humeri*, right, 5 adult and 2 young; left, 10 adult, 1 young (not corresponding with either of those of the opposite side). *Radii*, right, 14 adult, 3 young; left, 17 adult, 1 young. *Ulnæ*, right, 14 adult, 2 young; left, 10 adult, 1 young. *Pelvic bones*, mostly very fragmentary, but showing evidence of at least 9 adult males, 5 adult females, and several children. *Femora*, as with the other long bones, there are very few pairs, thus showing that there were more individuals than the actual number of bones would indicate: right, 11 adult and 2 young, 1 nearly full grown, but without epiphyses, 1 younger; left, 17 adult and 6 young of various ages, from quite small children upwards. None of these six have corresponding bones of the opposite side, so there is evidence from the femora of at least 23 individuals. *Tibiæ*, 18 right and 19 left, all adult. *Fibulæ*, 12 right and 11 left adult, and 3 young.

One of the largest of the femora has the head greatly enlarged and deformed by chronic rheumatic arthritis. The lower articular surface was mostly broken away, but the portion that remained appeared healthy.

One of the left tibiæ shows throughout the shaft marked evidence of chronic periostitis, the surface being thickened and vascular. A bone of the opposite side, which might have been of the same individual, shows the same condition in a less marked degree.

These are the only pathological conditions observed in any of the bones.

The question that naturally occurs after the examination of these remains is, How did they get into the cave? The [illegible] of the bones, and of the objects which were found with them [illegible] to their belonging to the native Indian inhabitants, and [illegible] the races which have been introduced into the island during the last four hundred years. A cave of such small [illegible] could not stand upright, could scarcely [illegible] the regular habitation of such a large number of persons. [illegible] a place of sepulture, but from its inaccessible [illegible] more likely to have been a refuge to which [illegible] the tribe had fled for safety, and in a vain endeavour to escape the horrible massacres by which we know the great bulk of the native population perished, had met a scarcely less miserable fate. Other similar discoveries, which will doubtless be made in the future, may throw light upon this question, and it is satisfactory to know that the authorities of the Jamaica Institute are now alive to the importance of carefully examining and preserving all such evidence as may still remain of the ancient history of the island and its inhabitants. The communication was illustrated by sketches of the cave, made by Mrs. Frank Cundall.

ELECTRIFICATION AND DISELECTRIFICATION OF AIR AND OTHER GASES.[1]

§ 1. EXPERIMENTS were made for the purpose of finding an approximation to the amount of electrification communicated to air by one or more electrified needle points. The apparatus consisted of a metallic can 48 cms. high and 21 cms. in diameter, supported by paraffin blocks, and connected to one pair of quadrants of a quadrant electrometer. It had a hole at the top to admit the electrifying wire, which was 5·31 metres long, hanging vertically within a metallic guard tube. This guard tube was always metallically connected to the other pair of quadrants of the electrometer and to its case, and to a metallic screen surrounding it. This prevented any external influences from sensibly affecting the electrometer, such as the working of the electric machine which stood on a shelf 5 metres above it.

§ 2. The experiment is conducted as follows: One terminal of an electric machine is connected with the guard tube, and the

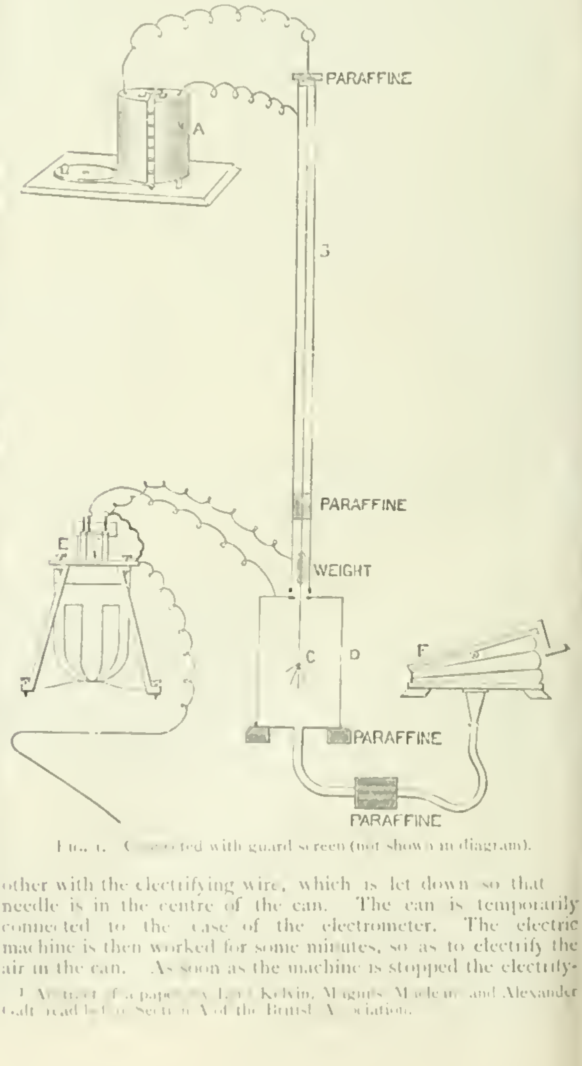

FIG. 1. Connected with guard screen (not shown in diagram).

other with the electrifying wire, which is let down so that needle is in the centre of the can. The can is temporarily connected to the case of the electrometer. The electric machine is then worked for some minutes, so as to electrify the air in the can. As soon as the machine is stopped the electrify-

[1] Abstract of a paper by Lord Kelvin, Magnus Maclean, and Alexander Galt, read before Section A of the British Association.

ing wire is lifted clear out of the can. The can and the quadrants in metallic connection with it are disconnected from the case of the electrometer, and the electrified air is very rapidly drawn away from the can by a blowpipe bellows arranged to suck. This releases the opposite kind of electricity from the inside of the can, and allows it to place itself in equilibrium on the outside of the can and on the insulated quadrants of the electrometer in metallic connection with it.

§ 3. We tried different lengths of time of electrification and different numbers of needles and tinsel, but we found that one needle and four minutes of electrification gave nearly maximum effect. The greatest deflection observed was 936 scale divisions. To find, from this reading, the electric density of the air in the can, we took a metallic disc, of 2 cms. radius, attached to a long varnished glass rod, and placed it at a distance of 1·45 cm. from another and larger metallic disc. This small air condenser was charged from the electric light conductors in the laboratory to a difference of potential amounting to 100 volts. The insulated disc thus charged was removed and laid upon the roof of the large insulated can. This addition to the metal in connection with it does not sensibly influence its electrostatic capacity. The deflection observed was 122 scale divisions. The capacity of the condenser is approximately $\frac{\pi \times 2^2}{4\pi \times 1·45} = \frac{1}{1·45}$. The quantity of electricity with which it was charged was $\frac{1}{1·45} \times \frac{100}{300} = \frac{1}{4·35}$ electrostatic unit. Hence the quantity to give 936 scale divisions was $\frac{1}{4·35} \times \frac{936}{122} = 1·7637$.

The bellows was worked vigorously for two and a half minutes, and in that time all the electrified air would be exhausted. The capacity of the can was 16,632 cubic centimetres, which gives, for the quantity of electricity per cubic centimetre, $\frac{1·7637}{16,632} = 1·06 \times 10^{-4}$. The electrification of the air in this case was positive: it was about as great as the greatest we got, whether positive or negative, in common air when we electrified it by discharge from needle points. This is about four times the electric density which we roughly estimated as about the greatest given to the air in the inside of a large metal vat, electrified by a needle point and then left to itself, and tested by the potential of a water-dropper with its nozzle in the centre of the vat, in experiments made two years ago and described in a communication to the Royal Society in May, 1894.[1]

§ 4. In subsequent experiments, electrifying common air in a large gas-holder over water by an insulated gas flame burning within it with a wire in the interior of the flame kept electrified by an electric machine to about 6000 volts, whether positively or negatively, we found as much as $1·5 \times 10^{-4}$ for the electric density of the air. Electrifying carbonic acid in the same gas-holder, *whether positively or negatively*, by needle points, we obtained an electric density of $2·2 \times 10^{-4}$.

§ 5. We found about the same electric density ($2·2 \times 10^{-4}$) of *negative* electricity in carbonic acid gas drawn from an iron cylinder lying horizontally, and allowed to pass by a **U**-tube into the gas-holder without bubbling through the water. This electrification was due probably not to carbonic acid gas rushing through the stopcock of the cylinder, but to bubbling from the liquid carbonic acid in its interior, or to the formation of carbonic acid snow in the passages and its subsequent evaporation. When carbonic acid gas was drawn slowly from the liquid carbonic acid in the iron cylinder placed upright, and allowed to pass, without bubbling, through the **U**-tube into the gas-holder over water, no electrification was found in the gas unless electricity was communicated to it from needle points.

§ 6. The electrifications of air and carbonic acid described in §§ 4 and 5 were tested, and their electric densities measured by drawing by an air pump a measured quantity of the gas[2] from the gas-holder through an india-rubber tube to a receiver of known efficiency and of known capacity in connection with the electrometer. We have not yet measured how much electricity was lost in the passage through the india-rubber tube. It was not probably nothing; and the electric density of the gas before leaving the gas-holder was no doubt greater, though perhaps not much greater, than what it had when it reached the electric receiver.

§ 7. The efficiency of the electric receivers used was approximately determined by putting two of them in series, with a paraffin tunnel between them, and measuring by means of two quadrant electrometers the quantity of electricity which each took from a measured quantity of air drawn through them. By performing this experiment several times, with the order of the two receivers alternately reversed, we had data for calculating the proportion of the electricity taken by each receiver from the air entering it, on the assumption that the proportion taken by each receiver was the same in each case. This assumption was approximately justified by the results.

§ 8. Thus we found for the efficiencies of two different receivers respectively 0·77 and 0·31 with air electrified positively or negatively by needle points; and 0·82 and 0·42 with carbonic acid gas electrified negatively by being drawn from an iron cylinder placed on its side. Each of these receivers consisted of block tin pipe, 4 cms. long and 1 cm. diameter, with five plugs of cotton wool kept in position by six discs of fine wire gauze. The great difference in their efficiency was no doubt due to the quantities of cotton wool being different, or differently compressed in the two.

§ 9. We have commenced, and we hope to continue, an investigation of the efficiency of electric receivers of various kinds, such as block tin, brass, and platinum tubes from 2 to 4 cms. long, and from 1 mm. to 1 cm. internal diameter, all of smooth bore and without any cotton wool or wire gauze filters in them; also a polished metal solid, insulated within a paraffin tunnel. This investigation, made with various quantities of air drawn through per second, has already given us some interesting and surprising results, which we hope to describe after we have learned more by farther experimenting.

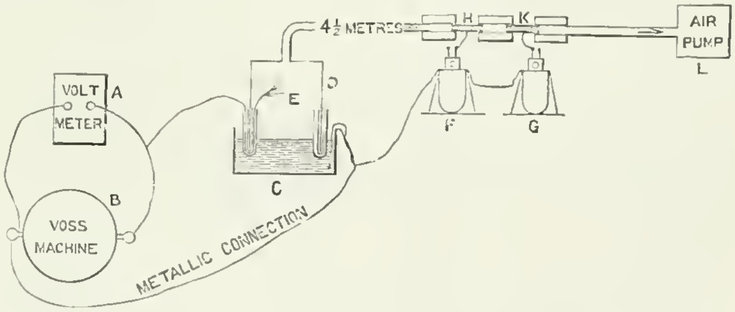

FIG. 2.

§ 10. In addition to our experiments on electric filters we have made many other experiments to find other means for the diselectrification of air. It might be supposed that drawing air in bubbles through water should be very effective for this purpose, but we find that this is far from being the case. We had previously found that non-electrified air drawn in bubbles through pure water becomes negatively electrified, and through salt water positively. We now find that positively electrified air drawn through pure water, and negatively electrified air through salt water, has its electrification diminished but not annulled, if the primitive electrification is sufficiently strong. Negatively electrified air drawn in bubbles through pure water, and positively electrified air drawn through salt water, has its electrification augmented.

§ 11. To test the effects of heat we drew air through combustion tubes of German glass about 180 cms. long, and 2½ or 1½ cms. bore, the heat being applied externally to about 120 cms. of the length. We found that, when the temperature was raised to nearly a dull red heat, air, whether positively or negatively electrified, lost little or nothing of its electrification by being drawn through the tube. When the temperature was raised to a dull red heat, and to a bright red, high enough to soften the

[1] "On the Electrification of Air," by Lord Kelvin and Magnus Maclean.

[2] The gas-holder was 58 cms. high and 81 cms. in circumference. Ten strokes of the pump raised the water inside to a height of 8·1 cms., so that the volume of air drawn through the receivers in the experiments was 42[illegible] cubic centimetres per stroke of the pump. This agrees with the measured effective volume of the two cylinders of the pump.

glass. Losses up to as much as four-fifths of the whole electrification were sometimes observed, but never complete diselectrification. The results, however, were very irregular. Non-electrified air never became sensibly electrified by being drawn through the hot glass tubes in our experiments, but it gained strong positive electrification when pieces of copper foil, and negative electrification when pieces of carbon, were placed in the tube, and when the temperature was sufficient to powerfully oxidise the copper or to burn away the charcoal.

§ 12. Through the kindness of Mr. E. Matthey, we have been able to experiment with a platinum tube 1 metre long and 1 milimetre bore. It was heated either by a gas flame or an electric current. When the tube was cold, and non-electrified air drawn through it, we found no signs of electrification by our receiver and electrometer. But when the tube was made red or white hot, either by gas burners applied externally or by an electric current through the metal of the tube, the previously non-electrified air drawn through it was found to be electrified strongly positive. To get complete command of the temperature we passed a measured electric current through 20 centimetres of the platinum tube. On increasing the current till the tube began to be at a scarcely visible dull red heat, we found but little electrification of the air. When the tube was a little warmer, so as to be quite visibly red hot, large electrification became manifest. Thus 60 strokes of the air-pump gave 45 scale divisions on the electrometer when the tube was dull red, and 395 scale divisions (7 volts) when it was a bright red (produced by a current of 30 amperes). With stronger currents, raising the tube to white-hot temperature, the electrification seemed to be considerably less.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—There are few changes of importance in the lists of lectures issued by the Board of Faculty of Natural Science for Academical year.

Prof. Gotch has come into permanent residence, and has appointed Dr. Gustav Mann, of Edinburgh University, to be Demonstrator in Physiology, in place of Dr. Pembrey, who has been appointed Lecturer in Physiology at the Charing Cross Hospital.

The new pathological laboratory in the Department of Regius Professor of Medicine is approaching completion, and Dr. J. Ritchie will give a course of practical Pathological Bacteriology for the Regius Professor. The present pathological laboratory is on a modest scale, and it is hoped that before long the University will be in a position to afford a building and equipment more worthy of the growing needs of the medical school at Oxford.

The examination for the Burdett-Coutts' Scholarship is to begin on October 21. There are this year two scholarships to be awarded, as none was awarded last year.

Mr. Frederic Lucien Golla, of Tonbridge School, has been elected to a Demyship in Natural Science at Magdalen College.

Four scholarships are announced for election at Wadham College on December 1, 1895, and in addition the Warden and Fellows have power to give exhibitions of £30 to £40 a year. No papers in Natural Science will be set, but in the case of one of the exhibitions preference will be given to any candidate who shall undertake to read for honours in Natural Science, and to proceed to a degree in Medicine in the University of Oxford.

Cambridge.—The election to the vacant professorship of Botany will take place on Saturday, November 2, at 2.30 p.m. Candidates are to send their names and testimonials to the Vice-Chancellor, Sidney Sussex Lodge, by October 26. The electors are Dr. Vines, Mr. Sedgwick, Dr. Allbutt, Dr. D. Oliver, Dr. Phear, Mr. F. Darwin, Sir J. D. Hooker, and Prof. Foster.

The election of a head of a college to be an elector to the Sadleirian Professorship of Pure Mathematics will take place on Tuesday, October 22, at 1 p.m. The vacancy is caused by the resignation of Dr. Phear, late Master of Emmanuel. The electors are those persons whose names are on the electoral roll of the University. Dr. Ferrers, of Caius, and Dr. Taylor, of St John's, are the present "heads" on the board of electors to the professorship.

Mr. C. T. R. Wilson, of Sidney Sussex College, has been appointed assistant demonstrator of experimental physics in the place of Mr. Capstick, resigned.

The Clerk Maxwell Scholarship in Physics is vacant by the resignation of Mr. Whetham. Candidates are to apply to Prof. Thompson, at the Cavendish Laboratory, by November 1. The scholarship is worth about £180 a year, and is tenable for three years. Candidates must be members of the University who have worked for a term or more at the Cavendish Laboratory.

Among the Fellows of Trinity College elected on October 10, are Mr. C. P. Sanger, bracketed second wrangler 1893; the Hon. W. Russell, bracketed eighth wrangler 1893; and Mr. I. L. Tuckett, first class Parts I. and II. Natural Sciences Tripos, and Coutts Trotter student in physics and physiology. Mr. Sanger and Mr. Russell were also placed in the first class of Part II. of the Moral Sciences Tripos 1894.

The London University Guide for the year 1895-96 has just been published by the University Correspondence College Press.

Dr. Dunn, head master of the Plymouth Technical Schools, has been appointed principal of the Northern Polytechnic Institute, Holloway Road.

Mr. Henry Louis has been elected Professor of Mining at the Durham College of Science, Newcastle-upon-Tyne, by a Joint Committee nominated by the College and the Coal Trades Associations of Durham and Northumberland.

The October *Record* of Technical and Secondary Education contains an illustrated article on the Yorkshire College, Leeds; and also a comparative summary of recent progress in technical education in various counties. This latter article continues and concludes a review of the work done by the Technical Education Committees of the English counties, commenced in the April number of the *Record*.

The entrance scholarships at the London Hospital Medical School have been awarded as follows:—Price scholarship in science, £120, Mr. H. Balean; Science scholarships, £60 and £35, Mr. O. Eichholz and Mr. A. B. Soltau; Price scholarship in anatomy and physiology, for university students, £60, Mr. R. C. Wall and Mr. J. H. Evans.

The following awards have been made at St. Bartholomew's Hospital:—Scholarship of £75 in biology and physiology, to Mr. C. S. Myers; scholarship of £75 in chemistry and physics, to Mr. J. S. Williamson; scholarship of £150 in biology, chemistry, and physics, to Messrs. R. C. Bowden and R. H. Paramore; preliminary scientific exhibition of £50 in biology, chemistry, and physics, to Mr. J. C. M. Bailey.

At St. Mary's Hospital Medical School the two university scholarships, of the value of £52 10*s*. each, have been awarded to Mr. R. Wade and Mr. G. S. Keeling; the first natural science scholarship, value £105, has been awarded to Mr. W. H. Willcox, and the three value £52 10*s*. each to Mr. H. Lovell-Keays, Mr. E. W. Holyoak, and Mr. A. F. Hayden.

At St. George's Hospital Medical School, science entrance scholarships of £85 have been awarded to Mr. Herbert Stringfellow Pendlebury, to Mr. Henry Goodridge Deller, and to Mr. John Howell Evans.

The following recent appointments are announced:—Prof. W. A. Setchell to the chair of botany in the University of California; Prof. H. Talbot to be associate professor of chemistry in the Massachusetts Institute of Technology; Dr. O. Jaekel, Privat-docent in geology in Berlin University, to be Extraordinary Professor; Dr. P. Lenard to the chair of physics in the Technische Hochschule at Aacheen.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xvii. No. 4 (Baltimore, October).—On the deformation of thin elastic wires, by A. B. Basset. In the author's previous paper (vol. xvi.) on the deformation of thin elastic plates and shells, whilst commending the novelty, power and elegance of the *geometrical* investigations employed in Mr. Love's treatise on elasticity, he impugned the treatment of the *physical* portion of the subject. It is on the same ground of defective treatment that Mr. Basset considers that a further exposition on the theory of wires is needed, and this is what is furnished in the present paper. A useful table of contents precedes the text. Investigations in the lunar theory, by Prof. E. W. Brown, is a memoir to which reference has already been made in our columns (No. 1352, p. 533). The closing paper is by Otto Staude, "Ueber den Sinn der Windung in den Singularen Puncten einer Raumcurve."

Bulletin de l'Académie Royale de Belgique, No. 6.—The conditions under which hydrogen peroxide is decomposed, by W. Spring. The catalysis of hydrogen peroxide takes place without chemical action by contact with various substances when the formation of water is favoured. Any substance which is more easily impregnated with water than with H_2O_2 brings about the decomposition of the latter. A solution of H_2O_2 containing salts is the seat of a decomposition whose activity increases with the temperature.—Chemical study of eight earths of the Lower Congo, by E. Stuyvaert. The analysis of earths from Boma, Zenze, Banza-Kasi, Mayombe, and Vungu-Mumba proves that the soils of the Lower Congo, sandy as well as calcareous, are provided with reserves of phosphoric acid and potash which insure a high fertility. It is certain that in the territories where the disappearance of forests has not modified the rainfall, as in Mayombe, the cultivation of coffee, cocoa, and other economic plants can be carried on for a long time without the use of manure.—On the critical temperatures of solution and their application to general analysis, by L. Crismer. The critical temperatures of solution may be used for the identification of chemical bodies without the necessity of weighing them, and they form a valuable additional criterion for the purpose of qualitative analysis. The critical temperature of solution is independent of the amount of either body present. It varies very much from one substance to another, but is constant for the same substance. For a mixture of two bodies, it is sensibly equal to the arithmetical mean of those of the constituents taken singly. Just as the surface tension of a liquid is reduced to zero at the critical temperature of vaporisation, so the surface tension of the lower liquid tends towards zero at the critical temperature of solution, and the meniscus separating them becomes a plane. An optical method of determining these critical temperatures may be based upon this fact.

Wiedemann's Annalen der Physik und Chemie, No. 9.—Double refraction of electromagnetic rays, by Peter Lebedew. The author succeeded, by a modification of Hertz's apparatus, in dealing with waves not more than 0·6 cm. long, and in demonstrating the phenomena of polarisation, reflection, and refraction with apparatus of the size ordinarily used in optics. The resonator used was a small thermo couple of iron and "constantane." An ebonite prism 1·8 cm. long showed refraction to within 3° of arc. Rhombic sulphur showed measurable double refraction, and a "Nicoll prism" was successfully constructed of two sulphur prisms with a plate of ebonite in place of the Canada balsam.—Luminescence of organic substances in the three states, by E. Wiedemann and G. C. Schmidt. Many organic vapours show true fluorescence, and some, like naphthalene, give composition spectra under the electric discharge, without being dissociated. Kathode luminescence is shown by many organic liquids, and the colour corresponds to that of the vapour. But the luminescence of the solid bodies often differs from that in the liquid state. Solid anthracene shows green, gaseous anthracene blue luminescence.—A vibration galvanometer, by H. Rubens. This instrument somewhat resembles Wien's optical telephone, and is used for measuring the intensity of alternating currents. It consists of a soft iron armature attached to a stretched wire. This executes torsional vibrations which are timed to the period of the alternating current. The latter traverses four electromagnets ranged round the armature, and when the periods are identical the armature executes strong torsional vibrations whose amplitude is measured by the width of a slit as seen reflected in a mirror attached to the wire. This arrangement is much more sensitive than the electrodynamometer.—Theory of the broadening of spectrum lines, by B. Galitzin. The molecular theory is superior to those based upon Doppler's principle, upon Kirchhoff's law, or upon damping. It admits of a development based upon the electromagnetic theory, that of molecular resonators. The broadening is a consequence of the forced vibrations produced by the collision of molecules. The want of symmetry of the broadening, and the influence of temperature and pressure are immediate consequences of the molecular theory as developed by the author.

THE numbers of the *Journal of Botany* for August–October contain several articles of interest to descriptive botanists. Mr. E. G. Baker concludes his revision of the African species of *Eriosema*, and Mr. A. B. Rendle his description of Mr. Scott Elliot's tropical African orchids, including a large number of new species; Mr. D. Prain continues his account of the genus *Argemone*; Mr. E. A. L. Ballers contributes a list of Marine Algæ new to Britain; and Mr. Arthur Bennett some notes on British Characeæ. There are biographical notices of the late Profs. W. C. Williamson and C. C. Babington, with a portrait of the latter.

Boll. della Soc. Sismol. Ital., vol. i., 1895, No. 5.—Some observations made on Vesuvius on June 21, 1895, by M. Baratta.—Vesuvian notes (January–June 1895), by G. Mercalli.—Hydrothermal observations at Fiumecaldo from January to April 1895, by C. Guzzanti.—Notices of Italian earthquakes, April 1895. A valuable record of the observations of the first after-shocks of the Laibach earthquake of April 14 from a large number of Italian stations.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 2.—Prof. Raphael Meldola, F.R.S., President, in the chair. Mr. McLachlan exhibited, on behalf of Mr. Bradley, of Birmingham, the specimens of Diptera attacked by a fungus of the genus *Empusa*, of which an account had recently appeared in the *Entomologist's Monthly Magazine*. Mr. H. Tunaley exhibited specimens of *Lobophora viretata* from the neighbourhood of Birmingham. Specimens of the green dark form were shown in their natural positions on the bark, and specimens of the yellow form were shown on leaves on which they rested.—Mr. J. W. Tutt exhibited cases formed by a lepidopterous insect received from the Argentine Republic, which he said he recognised as being either identical with, or closely allied to, *Thyridopteryx ephemeræformis*, which did great damage to many orchard and forest trees in North America. Mr. Tutt also exhibited a series of *Lycæna ægon* captured by Mr. Massey, of Didsbury, on the mosses in Westmoreland. The males were remarkable in bearing two very distinct shades of colour. The females also differed considerably from the form occurring in the South of England. He also exhibited a long series of *Hydrœcia lucens*, captured in the mosses near Warrington, and for comparison a series of *Hydrœcia paludis*, and he read notes on the various specimens exhibited.—Dr. Fritz-Müller communicated a paper entitled "Contributions towards the history of a new form of larvæ of Psychodidæ (Diptera), from Brazil."—Baron Osten-Sacken communicated a paper, supplemental to the preceding one, entitled "Remarks on the homologies and differences between the first stages of Pericoma and those of the new Brazilian species."—The Rev. A. E. Eaton also contributed some supplementary notes to Dr. Fritz-Müller's paper.—Lord Walsingham, F.R.S., read a paper entitled "New Species of North American Tortricidæ." In this paper twenty-nine species were dealt with, of which twenty-six were described as new, from Florida, California, N. Carolina, Arizona, and Colorado. The paper also included certain corrections made by the author in the nomenclature of genera.

PARIS.

Academy of Sciences, October 7.—M. Janssen in the chair. On an ascension to the summit of Mont Blanc, and on the work carried out during the summer of 1895 on the "massif" of this mountain, by M. J. Janssen. The ascent is described, together with an account of the cloud phenomena observed during a day in the higher regions. Passing on to describe the 0·33 m. telescope about to be erected at the observatory, it is remarked that the parts, now all assembled at the summit, will be mounted as a polar siderostat. A 0·0 m. mirror is to be mounted with the telescope. The observer will control all movements from a chamber of observation, which will be heated as may be required. As the instrument could not be taken down and remounted, it was bodily moved on to a new base formed of strong plates frozen on to the ice, and its pendulum then beat as regularly as at Paris. Observations with a Duboscq two-prism spectroscope in this very dry atmosphere failed to show any rays of aqueous origin in the solar light. The observatory has suffered a slight downward settling towards Chamounix; this took place in 1893 and 1894, and the movement is now insignificant. (See Our Astronomical Column.)—Study of some meteorites, by M. Henri Moissan. Iron from Kendal county in Texas contained amorphous carbon, but neither graphite nor diamond. Iron from Newstead (Roxburghshire) yielded amorphous carbon and graphite, but not diamond. Déesite, found in 1866 in the Sierra Déesa in Chili, contained a form of graphite only. Caillite, iron from Toluca-Xiquipilso,

Meteorite of 1784 contained no variety of carbon. Iron from Novy-Urei, Krasnoslobodsk, Penza, Russia (fall of August 23, 1886), yielded black diamond only. A further sample of meteoric iron from Cañon Diablo gave transparent diamond. All three varieties of carbon have been found in this meteorite.—On hyperglycæmia and glycosuria following ablation of the pancreas, by M. R. Lepine.—On the integration of Hamilton's differential equations, by M. Paul Staeckel. Concerning the results shown in the paper, the author remarks: "There is the true generalisation of Liouville's theorem, which allows the utilisation of all progress in the integration of Hamilton's equations to find new types of integrable equations, that is, to form new linear elements of which the geodesic lines can be determined."—On parasitic electrodes, by M. G. Delvalez.—On the mechanical properties of alloys of copper and zinc, by M. Georges Charpy. The tensile strength increases with the percentage of zinc, attains a maximum at 43 per cent., and then decreases rapidly: the elongation before rupture also increases with the zinc, passes through a maximum at 30 per cent., and then rapidly diminishes.—On a carbide of glucinum, by M. P. Lebeau. Pure crystallised glucinum carbide has been prepared at the high temperature of the electric furnace. The properties of this carbide, more particularly its reaction with water resulting in its decomposition in the cold with the production of methane, resemble those of aluminium carbide C_3Al_4, hence support is given to the formula C_3Be_4. The atomic weight of glucinum must be near 14, and glucina becomes Be_2O_3.—Researches on the combinations of mercury cyanide with iodides, by M. Raoul Varet. A thermochemical paper dealing with iodocyanides. Iodocyanides in solution yield the isopurpurate reaction on addition of potassium picrate at 30° C. and turn red-litmus paper blue. These salts must then be of the type $HgCy_2.MCy.HgI_2$, and not like the chlorocyanides $MCl_2.2HgCy_2$. The transformation of the system $2HgCy_2 + MI_2$ into $HgCy_2 + MCy_2 + HgI_2$ absorbs on the average -0.3 Cal. in solution, a quantity surpassed by the heat of formation of $HgCy_2.MCy_2$, $+12.4$ Cal., with that of its union with yellow HgI_2 giving $+2.3$ Cal.

On the double decompositions of mercury cyanide and salts of alkaline and alkaline earthy metals, by M. Raoul Varet.—Action of air on grape must and on wine, by M. V. Martinand.—Deep dredgings made on the Caudan coast in the Gulf of Gascony during August 1895, by M. R. Koehler. Much material, which has not yet been thoroughly examined, was obtained from (*a*) depths of 300 to 600 metres, illustrating the change from littoral to profound faunas; (*b*) coralligenous depths on the abrupt cliff running parallel to the French coast; (*c*) the bottom of the deeper part of the Bay of Biscay.—On the effects of the winter of 1894–5 on the fauna of the coast, by M. Jourdain.—M. Resel communicated an extract from a memoir to the Minister of War on the storm at Besançon on July 1.

NEW SOUTH WALES.

Linnean Society, August 28.—Mr. Cecil W. Darley in the chair.—On the homology of the palatine process of the mammalian premaxillary, by R. Broom.—Botanical notes from the Technological Museum, Sydney, No. iv., by J. H. Maiden and R. T. Baker.—The Silurian Trilobites of New South Wales, with references to those of other parts of Australia. Part iii. *Phacopidæ*, by R. Etheridge and John Mitchell. This important family is represented in the Silurian rocks of Australia by five species of *Phacops*, and one of *Homalonotus*; of these four are [illegible]. The [illegible] forms are at present un[illegible].

CONTENTS.

THURSDAY, OCTOBER 24, 1895.

THE METALLURGY OF IRON.

The Metallurgy of Iron and Steel. By Thomas Turner, Associate of the Royal School of Mines. Vol. i. "The Metallurgy of Iron." (London: Charles Griffin and Co., Limited, 1895.)

THIS is the third volume of a valuable series of treatises on metallurgy, written by Associates of the Royal School of Mines, under the able editorship of Prof. Roberts-Austen. It occupies an intermediate position between a text-book and an exhaustive treatise, and is intended not only for the use of the student, but also of persons who are connected with the manufacture of iron and steel, and who, therefore, may be assumed to have already some knowledge of the subjects discussed.

The attempt made by the author to compress within the space of 367 pages a useful account of this vast subject—the metallurgy of iron—has been satisfactorily accomplished; and although in some of the chapters the condensation is perhaps unduly great, yet this fault is minimised by the numerous references, which abound in the text, to original papers where full details may be found. In preparing these references, the author appears to have made a painstaking research into the literature of the entire subject, and this, together with his practical knowledge of its chief branches, has resulted in the production of a valuable treatise, which covers the whole field of the metallurgy of iron more completely than any other book in our language. As a standard of reference for detailed information, the *Journal* of the Iron and Steel Institute has been wisely chosen, as in it all advances in the metallurgy of the metal are recorded, and the more important are dealt with by specialists of note: it is, besides, easily accessible.

The volume begins with a patiently compiled summary of the history of iron, in which the origin and development of the metallurgical processes for the production and purification of the metal, and of the furnaces and appliances used, are clearly traced from the earliest times up to the present day.

A condensed *résumé* of the nature, composition and characteristics of the chief iron ores, and of the modes of preparing them for smelting, follows in chapters iv. and v. In a future edition the latter chapter might be extended with advantage, for, although no important methods are omitted, the descriptions of some are very brief.

The next five chapters (vi., vii., viii., ix. and x.) deal respectively with the blast furnace, the blast, the reactions which occur in smelting, the fuels used, and slags and fluxes. The general arrangement of a blast furnace plant is illustrated by sketch plans of a modern Cleveland and American (Edgar Thomson) works, and under "Construction of the Blast Furnace" a typical furnace of each of these works is selected for detailed description. The marked differences which are found in the internal lines and dimensions of the furnaces of the two countries, and in their practical working, are compared, and the reasons which have been advanced in favour of each are clearly stated and discussed; all of which tend to demonstrate that there can be no universal standard form, size, or method of working for a blast furnace. There are, however, undoubtedly some points in American practice which might be adopted with advantage in this country.

The diagram given on p. 127, illustrating the application of the recording pyrometer, as devised by Prof. Roberts-Austen, for the measurement of the temperature of the hot blast, is instructive, and shows conclusively the value of this instrument to the blast furnace manager.

The reactions which take place in the blast furnace, and the conditions which regulate the consumption of fuel, are very fully considered. Here the editor has allowed the author to state his own view of the theory of reduction, probably because it is evidently a "theory." It differs from that which Prof. Roberts-Austen is known to teach in his lectures at the Royal School of Mines. In chapters xi. and xii. the "Properties of Cast Iron" and "Foundry Practice" are discussed with a thorough knowledge of the subjects, both chapters being full of important matter. The effects of the presence of other elements, especially of silicon, on the physical characters of cast iron, are ably and comprehensively set forth, and experimental data of much value to the practical founder are given in demonstration of the relations which exist between the chemical composition of the metal and its fitness for special purposes. The necessity for a knowledge also of the relations between its hardness and strength is wisely insisted on, as, when these are fully grasped, the iron-founder requires only the information how to harden or soften his metal at will by the use of silicon or other agents, to produce castings in which the crushing, transverse and tensile strength, or othe characters, shall predominate as desired. These chapters deserve the careful study not only of the student, but also of the practical man, if he wishes to work intelligently, and so avoid the uncertain results which follow the "rule-of-thumb" methods still too often practised in our foundries. In no other text-book are the subjects of these chapters so lucidly and completely treated.

A description of the methods for the "Direct Production" of wrought iron—the subject of numerous modern patents, and of probably more failures—follows: and the three next chapters (xiv., xv. and xvi.) deal with the "Indirect Production" of the metal. Of these, the chapter devoted to "Puddling" is one of the best in the book. The account of the process and its various modifications it contains is worthy of high commendation. The concise descriptions and explanations which are given, many of which are based on the author's personal experience and investigations, and the useful practical suggestions which abound regarding the relative economy and extent of purification resulting from modifications in the method of conducting the process, cannot fail to be of great value to all iron-workers.

The corrosion of iron, a subject of not a little importance when we consider the disastrous results which may arise from the oxidation of a boiler-plate, a girder, a rivet, or a wire rope, is reserved for the last chapter of the book. The conditions under which this change occurs, the methods which are adopted for preventing or retarding it, and the experimental data on which these are founded, are carefully summarised here.

The book, however, is too good to be dismissed with commendation alone, and it would be unfair to its author and readers if we omitted to indicate one or two points in which its value may be increased in a future edition, which will doubtless be soon required. The illustrations are a weak feature of the book; several are unsatisfactory, being either rough in execution, wanting in detail, or too small in size, and a few can serve no useful purpose. We are sure the student would be grateful for the improvement of some, the omission of others, and the substitution for them of working drawings, not diagrams. We trust the author will bear this in mind in the preparation of his companion volume on steel.

The other faults are few and of a minor character. They are chiefly those of excessive condensation in the sections dealing with the blast furnace. These sections might be usefully expanded by the insertion of additional details respecting the actual erection of a furnace; also of an example of actual working similar to the excellent *résumé* given of the process of puddling.

The book, however, is an excellent one, thoroughly up to date, and a welcome addition to modern metallurgical literature. We can confidently recommend it to metallurgical students and all concerned with the manufacture and use of iron.

W. Gowland.

THE LIFE OF RENNELL.

Major James Rennell and the Rise of Modern English Geography. By Clements R. Markham, C.B., F.R.S. (The Century Science Series.) (London: Cassell and Co., 1895.)

"JAMES RENNELL was the greatest geographer that Great Britain has yet produced." This, the first sentence of the preface, is the text of the biography. The authority of the President of the Royal Geographical Society, himself the leading geographer of the day in this country, may be accepted as sufficient evidence of Rennell's pre-eminence. The name would perhaps not suggest itself to one who had a less thorough knowledge of the rise of modern English geography; for until the publication of this little volume, Rennell was without any more pretentious memorial than an obituary notice or a paragraph in a biographical dictionary. Mr. Markham writes with an enthusiastic singleness of aim; intent on illustrating his theme, he has perhaps on one or two occasions failed to criticise his own conclusions very severely before accepting them. Possibly he may unconsciously have applied the method *post hoc ergo propter hoc* in connecting all British progress in geography during the last fifty years with a name which cannot be found to be familiar even amongst professed geographers. Indeed we believe that this happily-timed biography will make Rennell's example more fruitful in results in the next few years than it has been during the sixty-five which have elapsed since the death of the great geographer.

The time is appropriate, for the recent meeting of the International Geographical Congress in London has brought into public notice the superiority of other nations in the organised study of geography as a branch of science definite and distinct from others, capable of being cultivated by research and of being applied to numberless practical purposes.

Mr. Markham repudiates the suggestion that Major Rennell was an "arm-chair geographer"; but we are not sure that this somewhat hackneyed term is necessarily one of reproach. Rennell was greatest as a student and a critic, and by the practical experience of his earlier life he fitted himself to speak *ex cathedra* on questions, where insight and judgment were required to interpret, even to the travellers themselves, the full meaning and importance of their journeys. A professor's chair would have been his true place.

The greatness of Major Rennell may best be understood by a glance at the mileposts of his life. He was born in 1742, at Chudleigh, in Devon, and at the age of fourteen he joined the Navy, where he saw some service and learned to survey. In 1760 he went out to India as a midshipman; but after three years' hard work, largely occupied in surveying in the Indian Ocean, he left the Navy, joined the East India Company's service, and received the command of a ship. As if by a stroke of magic he was nominated Surveyor-General of Bengal and gazetted an ensign in the Bengal Engineers in 1764, when only twenty-one years of age. In this new and congenial sphere he worked devotedly for thirteen years, personally surveying the most unhealthy part of India with such success that in 1779 he published the "Bengal Atlas" containing the first authentic maps of the province. He left India in 1777, and, settling in London, devoted himself to critical geographical studies. His first purely geographical work was a "Memoir to the Map of Hindostan," and the map itself. In 1781 he became a Fellow of the Royal Society, and subsequently he communicated two papers to the *Philosophical Transactions.* Although ignorant of the classical languages, he studied the works of the Greek geographers in translations, and so produced his famous "Geography of Herodotus" and "Comparative Geography of Western Asia." Then turning to the burning question of his time in geography, the penetration of Africa, he pieced together the information brought home by Ledyard, Hornemann, Mungo Park, and other explorers sent out by the African Association. Here the results of subsequent discovery did not always confirm the provisional conclusions he arrived at from a critical study of the data at his disposal, but his controversies as to the course of the Niger interest the world no more.

Mr. Markham considers that Rennell was "the founder of another branch of the science of geography, which has since been called oceanography"; yet we find in Dr. Murray's compendious history of oceanography in the summary of the scientific results of the *Challenger* Expedition, a much more ancient lineage for that branch of science, and in the record of its development Rennell's name is not even mentioned. He certainly succeeded in calling attention to the importance of ocean currents, and made many shrewd observations as to their origin, preparing the way for the wider generalisations of Maury. He strongly held the theory that ocean currents are primarily due to the prevailing winds; and it is interesting to notice that the particular current issuing from the Bay of Biscay, to which his own name is attached, should only last year have been shown by Hautreux to have no permanent place, but to vary in force and direction with the changes of the wind.

It would be impossible to notice the numerous memoirs by which Major Rennell impressed the learned world of his time. With Sir Joseph Banks and other friends, he formed a sort of social circle for travellers and scientific men, which led to the formation of the Raleigh Club in 1827, and may be said to have formed the nucleus of the Royal Geographical Society established three years later.

Rennell's training was purely a practical one in the hard work which gave him a mastery of the technicalities of surveying and map-construction. Knowing the actual forms of sea and land at first hand, able himself to delineate them with exceptional skill, he could not make the mistakes which beset the merely theoretical student. This is still the one way to become a practical geographer, only in the present day a working knowledge of geology must be added to proficiency in the arts of observation and measurement. On such a foundation, so gained, theoretical instruction may profitably be superimposed. Mere lectures on theoretical geography, isolated lessons in the use of instruments, do not suffice to make a man a geographer, any more than lectures on theoretical chemistry and a few repetitions of the routine of simple analysis will make a man a chemist. If British geographers are to catch up and keep pace with those of the continent, they must receive systematic training in their student days, and take up geography as a serious study, as one takes up any other science. For, alas, the good old days are gone, and there is no Warren Hastings on the threshold of the twentieth century to confer pensions of £600 at the age of thirty-five on the would be Rennells of to-day! As geological students have to follow other methods than those of Murchison, so present-day geographers cannot take Rennell too literally as their model; and Mr. Markham plainly states that he looks to the labours of the University lecturers in geography to maintain the succession of British geographers. If this is to take place, there must be fresh organisation and encouragement of pure geographical research on the part of the Universities. Much progress is improbable as long as the antithesis between "geography" and "science" is a possible figure of speech. It is not so in Germany.

HUGH ROBERT MILL.

COUNTER-IRRITATION.

The Theory and Practice of Counter-Irritation. By H. Cameron Gillies, M.D. (London: Macmillan and Co., 1895.)

DR. GILLIES has selected a subject rich in literature but poor in experiment, and has treated it entirely from the literary as opposed to the experimental side. The first part of the book is devoted to a *résumé* of the literature of counter-irritation, and inflammation, which Dr. Gillies rightly considers he must not only quote, but criticise. Some of his criticisms we do not understand, some are entirely superfluous, Dr. Gillies taking up much space in demolishing theories which in the present day nobody could possibly believe in, some—and two of these we shall consider—show a want of scientific understanding.

On page 73, our attention is drawn to a paper by Dr. Hollis, published in the St. Bartholomew's Hospital Reports for 1874. Dr. Hollis showed that vesication could be produced in the Actiniæ by the local application of liquor ammoniæ. The importance of these researches consisted in the fact that they demonstrated that the living cell itself, using this term in its general sense, was capable of reacting to an irritant. It is to work done exactly on these lines by Metschnikoff[1] that we owe the modern theory of Phagocytosis. The physiology, the pharmacology, and the chemistry of the cell are presumably to Dr. Gillies, as "provoking" as he admits Dr. Hollis' monograph to be. The second class of experiments performed by Dr Hollis demonstrated that local reaction to irritants took place in the excised tail of a newt, thus showing that this local reaction was independent of the general circulation. Dr. Gillies objects to "all such experiments, not only upon moral and humane grounds, but on the ground also that we have not been able to make sure that any good has come by them." "The tail is either dead or living, if living the result only shows that it is a living result; if dead we are not as physicians concerned with the chemistry of the action."

On page 78, our author considers an article by Dr. Lauder Brunton in the St. Bartholomew's (not the St. George's) Hospital Reports for 1875. Dr. Gillies differs from the author upon two points. First, he (Dr. Gillies) denies that inflammation can occur independently of congestion. One would have thought that this had been settled by Hollis. The discrepancy is explained when one finds, after a page's reading, what Dr. Gillies means by congestion—"an acceleration of the processes of nutrition." When arguing with a physiologist it is as well to adopt the usual physiological terminology. The second point of difference is Brunton's dictum that "pain in an inflamed part is probably due to distension of the vessels and pressure on the nerves." "The characteristic pains of neuralgia so called," says Dr. Gillies "are not easily if at all referable to the pressure from active congestion." Is a nerve which is the seat of neuralgia an inflamed part?

Dr. Gillies evidently believes that "he alone destroys who rebuilds," so we are not left merely amongst the ruins of other theories, but are provided with a "new" one. "Whatever good comes by the use of counter-irritants is because, by their irritant effects, they stimulate the activity of the tissues of the part to which they are applied and accelerate the blood supply thereto, so increasing nutrition or repair, as the need may be." This is the only new theory which we have been able to extract from chapter vii. What about the remote effects of counter-irritants? If Dr. Gillies is convinced that whether directly or remotely counter-irritants act beneficially only when they directly, or reflexly, increase the blood supply, that is at least a coherent theory; we think it quite probable that irritation of a given skin area by a blister or otherwise can give rise to reflex dilatation of the corresponding vascular area. Bradford[2] actually observed dilatation of the vessels of the kidney upon stimulating the central ends of the posterior roots of the so-called renal area, whereas stimulation of the central end of an intercostal nerve always caused contraction. Dilatation of the vessels of the splanchnic

1 "Leçons sur le Pathologie comparée de l'inflammation."
2 *Journal of Physiology*, vol. x. 4 4.

area has been observed upon stimulation of the central end of the sciatic nerve during chloral[1] and pyridin[2] poisoning, showing the influence exerted by the condition of the centre at the time of peripheral stimulation.

Of the second, the so-called "practical" part of the book, we have little to say. From what we have read, we regard Dr. Gillies' practice as no sounder than his theories. The reprint with which he provides us of Dr. Davies' original communication on blistering in acute rheumatism, and the controversy thereon, is the most interesting part of the book. We should like to know who it is who believes that the "serum" is "*abundantly* charged with lactic acid" in acute rheumatism; and, supposing it was, how much one is likely to get from the serum, say, of half a dozen blisters? (p. 88.) To sum up our remarks, we do not consider the book of value either to physicians or physiologists. The facts it contains are not new, and the theories do not justify their existence, since they fail to fulfil the conditions which should be demanded of all hypotheses, viz. to indicate lines of research which shall offer a reasonable hope of increasing our knowledge. One merit which it possesses, is that it may draw attention to some valuable pieces of work which might perhaps otherwise have been disregarded.

F. W. T.

A NEW DEPARTURE IN GEOMETRY.

Die Grundgebilde der ebenen Geometrie. By Dr. V. Eberhard, Professor at the University of Konigsberg i. P. Bd. I. 8vo. xlviii. + 302 pp. Five plates. (Leipzig: Teubner, 1895.)

THE history of Analytical Geometry affords a curious subject of study to the thoughtful mathematician. It would seem that equations between coordinates were first used to express spatial relations discovered by intuitional processes, and the equations were combined algebraically to discover other implied spatial relations. For this purpose it was necessary to interpret in geometrical terms equations arrived at by algebraic processes from geometrical data, and the facility thus acquired led men to seek for similar interpretations of equations set down without reference to geometrical conditions. Hence it happens that modern developments of Analytical Geometry appear rather to present algebraic facts in geometrical language than to deduce results that can be apprehended by intuition from data of intuition. Such a notion as that of a cubic surface, for instance, would seem to be essentially analytical, and although it has been proved possible to arrange a geometrical construction for an algebraic curve whose equation is given, yet the construction arrived at is so artificial that intuition fails to grasp by its aid the necessary form of the curve. Looking at the subject in this way, it seems hardly too much to say that the algebra which was designed to be the servant of the geometer has become his master.

Some such reflections as these form the starting-point of Dr. Eberhard's work. The volume under notice is to be the first of a series, and in his long preface[3] he sets forth his aim and method. Here, after tracing the origin in experience of simple geometrical notions such as those of the straight line and the plane, he divides curves and surfaces into two classes, the regular (gesetzmässig) and the fortuitous (zufällig), and proceeds to inquire after intuitional criteria available for distinguishing between them. He defines a regular locus as one in which a relation that can be apprehended by intuition connects a variable point of the locus with a finite number of points fixed in it. The kind of relation which he admits as capable of being apprehended by intuition is essentially topographical. This will be elucidated by considering the example he gives. Let a system of points be taken, and let planes be drawn through them three by three. These planes will in general intersect in other points besides those of the original system. Let planes be now drawn through the points of the extended system three by three. These planes will again intersect in some new points, and the process can be continued. Let the process be arrested at any stage, and suppose a set of four points of the extended system lie in one plane. If one of the points of the original system were slightly displaced these four points would generally cease to lie in one plane, but if the particular point of the original system were displaced on a certain surface, the four points would remain in a plane. This property constitutes a definition of the surface available for intuitional geometry. It will be seen from the example that the method rests upon the topographical relations of systems of points.

The description of these relations for a given system can be carried out systematically, and the process consists in the use of two related notions. The first is the notion of "characteristics," and the second is the notion of the "index" of a point in a plane system. If three points out of four are taken in a definite order, the triangle formed by them is described in the positive or negative sense by an observer on the same side of their plane as the fourth point. The sense of description of the triangle formed by three points in a definite order for an observer on a definite side of their plane is the characteristic of the three. The index of a point in a plane system is the order in which a line turning about that point meets the other points of the system. A statement of the indices simplifies the problem of stating the characteristics.

The bulk of the present volume is taken up with theorems concerning the characteristics and index-systems of groups of points in a plane, and they are fully exemplified in the cases of groups of four, five, and six points. In an investigation of so novel a character we find, as we might expect, original methods of working and difficult arguments. The want of figures in illustration of the earlier chapters, and some of the notations employed, combine with the nature of the subject to render the book difficult to read.

The endeavour to make the geometry of curves and surfaces of high degrees more intuitive is laudable, a new classification of loci founded on geometric rather than algebraic principles is also a worthy object of research, and the idea of grounding such a classification in topographical circumstances is ingenious; but a final judgment as to Dr. Eberhard's success in these directions can only be pronounced after his complete work has been given to the world.

OUR BOOK SHELF.

Handbook of Grasses; treating of their Structure, Classification, Geographical Distribution, and Uses, also describing the British Species and their Habitats. By William Hutchinson. 8vo. Pp. 92, 40 woodcuts. (London: Swan Sonnenschein and Co. New York: Macmillan and Co., 1895.)

THIS is a cheap popular work, adapted for the use of elementary students. There is nothing that covers the same field in existence already, and it fulfils its purpose excellently well. It would have been better to have called it "An Introduction to the Study of the British Grasses," as it only deals in detail with the British species, which are not more than one-thirtieth of the total number of grasses that are known in the whole world. The short introduction explains how easily a collection of dried grasses can be made. The first chapter, called "Structure," gives all the different organs in detail, showing what is the general plan on which grasses are organised, and explaining the general and special terms which are used in describing the genera and species. In the second chapter, which is the longest in the book, the hundred and odd British species are classified according to their localities, and described in detail, most of the common kinds being illustrated by small woodcuts, with dissections. The third chapter is devoted to classification, in which Bentham and Hooker's "Genera Plantarum" is followed. The British genera are described in detail, and the characters of the thirteen tribes there adopted, several of which are not represented in Britain, are given. The rest of the book is occupied by a readable account of the geographical distribution of the grasses, especially of the cereals, and an account of their various uses for food, and in other ways. *Gramineæ* is one of the most universally distributed of all the natural orders of plants, and, in point of the number of species, is only exceeded by five other natural orders: *Compositæ*, *Leguminosæ*, *Orchideæ*, *Melastomaceæ*, and *Rubiaceæ*. Between three and four thousand species of grasses are known, and they are classified under three hundred genera. The little book is well written and trustworthy, and no doubt will secure a good circulation.

Rural Water Supply. By Allan Greenwell, A.M.I.C.E., and W. T. Curry, A.M.I.C.E. Pp. 210. (London: Crosby Lockwood and Son, 1895.)

IN this volume we have an elementary work on water engineering, containing a sufficient account of the principles and construction of waterworks to be of real use to engineers, and forming at the same time a good introduction to more elaborate treatises. The volume is based upon a series of articles which appeared in the *Builder* last year, and it contains valuable information upon all matters connected with water supply. It is, indeed, what its secondary title represents it to be, namely, "a practical handbook on the supply of water and construction of waterworks for small country districts." The book is full of details on points which are continually before waterworks engineers; and though these details are mostly rules and formulæ which have to be accepted without being understood, they will be of great assistance in planning schemes of water supply and in carrying out the works.

Climbing in the British Isles. II. Wales and Ireland. Wales. By W. P. Haskett Smith. *Ireland.* By H. C. Hart. Pp. 197. (London: Longmans, Green, and Co., 1895.)

CLIMBERS will find this little pocket-book an invaluable guide to instructive scrambles in Wales and Ireland; but the large number of fatal accidents recorded in its pages is hardly calculated to give other readers the mountaineering fever. On the first two pages of the book, three fatal falls and one severe accident are noted, and the tale of deaths is sustained throughout the book. To those who are filled with the desire to climb, this spice of danger only gives zest to the recreation; and the fact that several lives have been lost in attempts to scale a certain rock, is a sufficient reason for many Englishmen to tackle that rock and endeavour to scale it. In the book under notice, all the essential information about climbs in Wales and Ireland is given, with thirty-one illustrations (by Mr. Ellis Carr) and nine plans. By means of it, the would-be climber will be able to select his hills and peaks without difficulty, and with its assistance he may do in these islands hill-climbing which will form no mean part of a real mountaineering education. The book is primarily intended for those who climb for climbing's sake, hence little attention is paid to the geological interest of the rocks and hills described.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Feeding-Ground of the Herring.

IN his presidential address to Section D of the British Association at Ipswich, Prof. Herdman says:—

"Probably no group of animals in the sea is of so much importance from the point of view of food as the Copepoda. They form a great part of the food of whales, and of herrings and many other useful fish, both in the adult and in the larval state, as well as of innumerable other animals, large and small. Consequently, I have inquired somewhat carefully into their distribution in the sea, with the assistance of Prof. Brady, Mr. Scott, and Mr. Thompson. These experienced collectors all agree that Copepoda are most abundant, both as to species and individuals, close round the shore, amongst seaweeds, or in shallow water in the Laminarian zone over a weedy bottom. Individuals are sometimes extremely abundant on the surface of the sea amongst the plankton, or in shore pools near high water, where, amongst *Enteromorpha*, the Harpacticidæ swarm in immense profusion; but, for a gathering rich in individuals, species, and genera, the experienced collector goes to the shallow waters of the Laminarian zone. . . . In order to come to as correct a conclusion as possible on the matter, I have consulted several other naturalists in regard to the smaller groups of more or less free-swimming Crustacea, such as Copepoda and Ostracoda, which I thought might possibly be in considerable numbers over the mud. I have asked three well-known specialists on such Crustaceans—viz., Prof. G. S. Brady, F.R.S., Mr. Thomas Scott, F.L.S., and Mr. I. C. Thompson, F.L.S.—and they all agree in stating that, although interesting and peculiar, the Copepoda and Ostracoda from the deep mud are not abundant either in species or in individuals. In answer to the question which of the three regions, (1) the littoral zone, (2) from low water to 20 fathoms, and (3) from 20 fathoms onwards, is richest in small free-swimming, but bottom-haunting, Crustacea, they all replied the middle region from 0 to 20 fathoms, which is the Laminarian zone and the upper edge of the Coralline. . . . [Mr. T. Scott] tells me that as the result of his experience in Loch Fyne, where a great part of the loch is deep, the richest fauna is always where banks occur, coming up to about 20 fathoms, and having the bottom formed of sand, gravel, and shells. The fauna on and over such banks, which are in the Coralline zone, is much richer than on the deeper mud around them. On an ordinary shelving shore on the west coast of Scotland, Mr. Scott, who has had great experience in collecting, considers that the richest fauna is usually at about 20 fathoms."

It seems to me that these three specialists, or experienced collectors, have not given Prof. Herdman any information as to whether free-swimming Crustacea, such as Copepoda, are found in considerable numbers over the mud or not, as maintained by Dr. Murray in his concluding remarks in the Summary volumes of the *Challenger* Report, and I propose to answer the

question here. For ten years I have been engaged in dredging and trawling about the coasts of Scotland, chiefly as captain of Dr. Murray's yacht *Medusa*, and my experience does not coincide with that of Messrs. Brady, Scott, Thompson, and Herdman. For instance, in Loch Fyne I have always been able at any time of the year to collect in half an hour enormous numbers of *Euchæta*, *Calanus*, and *Nyctiphanes* over the mud in depths of about 70 fathoms or greater. Any person can see at the Millport Biological Station large bottles filled with these Crustaceans taken in a single haul. The stomachs of the herrings are frequently crammed with these Crustaceans, and the herrings certainly never got this food about the Laminarian zone, as suggested in Prof. Herdman's address.

Dr. David Robertson, who is one of the best-known collectors in the country, pointed out years ago that the Loch Fyne herrings got their food in the deep water, and attributed their fine quality to this fact. Dr. Robertson authorises me to say that, though there may be more species of Copepods in the Laminarian zone than in the deep water, still the number of individuals is very much greater in the deep water over the mud, as is conclusively proved by the *Medusa's* work.

Proper methods must, of course, be used, for I know of at least one instance in which a gentleman of considerable scientific repute was prepared to say that the free-swimming Crustaceans over the mud had completely left Loch Fyne; he communicated his opinion to Dr. Murray, with the result that the *Medusa* was ordered to Loch Fyne to investigate the matter. As was expected, the result was that these Crustaceans were found in as great profusion as on any previous occasion.

The result of my experience in Loch Fyne is that the nearer the nets are dragged to the mud in the deep water the greater will be the number of *Euchæta*, *Calanus*, and *Nyctiphanes* captured. I have taken, hundreds of times, in 70 fathoms, in a single haul lasting from twenty minutes to half an hour, more Copepods than can be collected in the Laminarian zone in eight or ten days. I have also captured herrings by means of drift nets sunk to the bottom in depths of 70 and 80 fathoms, and their stomachs were filled with Crustaceans of the same species as we captured by the nets just over the mud at these depths.

As to the deep mud in Loch Fyne not producing a rich fauna, I may state that in the deepest water the trawl could not be kept down for a longer time than about half an hour; otherwise the deck engine and all other appliances on board would have failed to bring the net to the surface through sheer weight, chiefly of organisms. There was generally a certain percentage of mud present, but the bag of the net was generally crammed with thousands of *Actinia*, which live there, along with *Pecten septemradiatus*, *Hippolyte*, *Pandalus*, *Crangon*, *Ascidians*, and many other invertebrates and fishes.

I have dredged Loch Fyne systematically for months, and examined its fauna from the littoral zone to the greatest depth; the specimens collected are now beside me, and all the journals with the notes are in Dr. Murray's possession. But I think enough has been said to show that the greatest abundance of Copepods is not to be found in the Laminarian or other shallow zones, but in the deep water over the mud; also that the deep mud does possess a very rich fauna. I speak only of the abundance of the above-mentioned organisms, with which I am well acquainted. I am not a specialist nor a scientific man, but I have had a great deal to do with the practical part of the investigations which have assisted Dr. Murray in drawing his conclusions.

ALEXANDER TURBYNE.

Millport, Cumbrae, N.B., October 5.

The Toronto Meeting of the British Association.

AN effort will be made to have the meeting of the American Association for the Advancement of Science held at San Francisco in 1897, so that the members of the British Association may cross the continent, and join us there, either before or after their own meeting at Toronto, which many of us hope to attend.

A suggestion of great importance, and deserving immediate consideration, seems to me that the Australasian Association should try to arrange a meeting for the same year on the Pacific coast of America, so that we may all join in the meeting of the American Association at San Francisco. This will be the first meeting of any of these Associations on that coast, and hence a momentous occasion.

I do not know how to reach the officers of the Australasian Association; but think that an insertion of this letter in NATURE will find them. I have already sent a letter at a venture to the President by his official title, as I do not know his name, in care of the Post-master of Melbourne, to be forwarded; but perhaps the Post-master may not know where to send it.

I have also written to Mayor Sutro of San Francisco, calling his attention to it.

WM. H. HALE.

Brooklyn, October 9.

The Theory of Magnetic Action upon Light.

IN the British Association Reports for 1893, Mr. Larmor has attempted to show that a satisfactory theory of magnetic action upon light can be constructed by means of a modification of Maxwell's theory which was proposed by Prof. Fitzgerald in 1879; and he alleges, with special emphasis (see p. 340), that his theory furnishes "a consistent scheme of equations of reflection and refraction, without the necessity of condoning any dynamical difficulties in the process." And on p. 350, after raising objections against a theory originally suggested by Prof. Rowland, and afterwards fully developed by myself, he says: "But against this procedure," that is my own, "there stands the pure assumption as regards discontinuity of electric force at an interface."

To fully discuss the defects of Larmor's resuscitation of Fitzgerald's theory would occupy too much space, and would necessitate the introduction of a considerable amount of mathematical analysis. I shall, therefore, confine myself to pointing out that his theory is open to exactly the same objections as my own, viz. *discontinuity of the tangential component of electromotive force at an interface.*

One of Larmor's boundary conditions (see p. 349) is equivalent to the condition that the expression

$$\frac{4\pi g}{K} + 4\pi\frac{Cd\beta}{d\theta} - 16\pi^2\pi C\gamma_0\frac{df}{dt}$$

should be continuous. Now $4\pi g/K = Q$, where Q is one of the tangential components of the E.M.F. at an interface; also in unmagnetised media $C = 0$. Consequently, if accented letters refer to the latter medium, the condition becomes

$$Q + 4\pi C d\beta/d\theta - 16\pi^2 C\gamma_0 df/dt = Q';$$

in other words, *the tangential component of the E.M.F. is discontinuous.*

The Society of Chemical Industry and Abstracts.

AT the recent annual meeting of the Society of Chemical Industry, the retiring President and the new President each made some remarks concerning the cost of the journal of the Society, and the necessity of curtailing expenses by dealing more strictly with the abstracts. I suppose hardly any two of us would quite agree as to what is the rubbish, Teutonic or otherwise, which ought to be left out, and what is good matter, which ought to be abstracted at greater or less length. No matter who is editor, all of us would abide as firmly as ever in the belief that we could have made a better selection of articles for abstraction. Before, however, we set about any further movement in the direction of cutting down abstracts to a mere useless list of titles, I would like to point out one direction in which expense might safely be curtailed without fear of objection from any quarter. All will agree, I am sure, that it is a waste of money to abstract the same article twice. I am sure other members besides myself must have noticed that this blemish is not entirely absent from the Society's journal. It should be known to every chemical babe and suckling, that even very unimportant papers are sometimes published more than once. Yet this seems to have escaped the notice of whoever is responsible for the editing of the abstracts. Witness the following from this year's journal:—P. 389, "Sulphides of Cobalt and Nickel, A. Villiers (*Bull. Soc. Chim.*, 1895, 13 [4])," and "*Qualitative* Separation of Nickel from Cobalt, A. Villiers, *Bull. Soc. Chim.*, 1895, 13 [4]." Now let us turn to p. 524, where we find, "Sulphides of Nickel and Cobalt, A. Villiers, *Comptes rend.*, 1894, 119," and on p. 509, "Qualitative Separation of Nickel and Cobalt, A. Villiers, *Comptes rend.*, 1895, 120." We have cobalt and nickel in one case, and nickel and cobalt in the other; but the articles from the *Bull. Soc. Chim.* are the same as those from the *Comptes rend.*, and by the same author. A still more incomprehensible example will

be found on comparing pp. 191 and 313. On p. 191 we have a short abstract of an article on petroleum, by A. Riche and G. Halphen. On p. 313 we have a long abstract of the same article. In one case it is given under *qualitative* organic chemistry, in the other under *quantitative* organic chemistry. Yet the reference in each case is the same—"*J. Pharm. Chim.*, 1894. 30, 289." In this case, therefore, the abstracts are not even prepared from different journals.

I would suggest, then, that the first reform which the Editing Committee might institute in carrying out their scheme of retrenchment, should be one placing a limit on the number of abstractors who are to deal with one and the same article, even when it occurs in different publications. JAMES HENDRICK.

Glasgow, October 2.

Note on the Dendrocolaptine Species, "Dendrexetastes capitoides" of Eyton.

IT recently became necessary for me to examine some of the Dendrocolaptine birds in this museum, and among them the species named above. Our specimen, the type of the genus *Dendrexetastes* founded by Eyton in 1851, in Jardine's "Contributions to Ornithology," on a skin from an unknown locality, formerly in Lord Derby's museum, has evidently been examined by Dr. Sclater, for its label bears, in the well-known calligraphics of that distinguished authority on this group, the name *Dendrexetastes temmincki*. The difficulty I have in ascribing our specimen to that species is the cause of this note. According to the fifteenth volume of the "British Museum Catalogue of Birds," by Dr. P. L. Sclater, the genus contains but two species, *D. temmincki* and *D. devillii*, which, by his key on p. 140, are distinguished from each other, the former by having "blackish cross-bands" on the belly, and the latter having that region "uniform brown." On consulting Eyton's original description in the "Contributions to Ornithology," I can find no mention of any cross-bands on the belly; for there are none on the skin, which is apparently that of a mature bird. In looking up next the description by Lafresnaye, in the "Revue de Zoologie" for 1851, of his *D. temminckii*, to which Dr. Sclater has relegated as a synonym Eyton's *D. capitoides*, I read:—" . . . . pectoris ventrisque plumis totis umbrinis, in medio maculâ triangulari-elongata nivea nigro marginata notatis; ventris maculis strictis; fere linearibus; subcaudalibus pallide rufescentibus, albo late, fuscoque anguste vittatis. . . ." These words, as I interpret them, make no mention of the presence of cross-bands on the belly of *D. temmincki*, while the latter half of the quotation, in regard to the under-tail-coverts being pale rufous, with broad white and narrow fuscous spots, does not apply to *D. capitoides*, for the type-skin before me presents no such characters. The plate illustrating Lafresnaye's description of the first-mentioned bird (*loc. sup. cit.*) shows its breast-spots to be much narrower, though not linear, and shorter than those in *D. capitoides*, while the spots on the feathers on the upper part of the belly can hardly be termed "fere linearibus," which they are, however, in *D. capitoides*. The lower belly in the plate, "plumis totis umbrinis," shows, just as in the last-mentioned species, not a single cross-band. It would appear to me, therefore, that *D. capitoides*, Eyton, can scarcely be = *D. temmincki*, Lafr., while the latter differs from *D. devillii* (of which I regret our museum does not possess a specimen), and, I take it, from *D. capitoides*, by its smaller and narrower throat-spots. The subcaudal characters separate *D. capitoides* from *D. temmincki*, and apparently the typical *D. devillii* is separated from it also by the "striis strictissimis" of the breast, and the very linear shaft-stripes of the upper neck feathers. Is *D. capitoides* = *D. devillii?* Or are there three species? I incline to the opinion that there are. HENRY O. FORBES.

The Museums, Liverpool, October 8.

The Pressure of a Saturated Vapour as an Explicit Function of the Temperature.

IT may be of some interest to note that Cailletet and Mathias' "Law of Diameters," in combination with any equation of state, such as Van der Waals', which applies to the region of coexistence of liquid and vapour, supplies an (empirical) expression for the maximum pressure of a vapour at any temperature T in the form of an explicit function of this temperature and known constants.

Let p, v and T denote the pressure volume and absolute temperature of unit mass of the substance. According to Van der Waals' original equation of state, we have then:—

$$\left(p + \frac{a}{v^2}\right)(v - b) = \mathrm{RT}.$$

If v_1, v_2, v_3 denote the roots of this cubic in v, we have:

$$v_1 + v_2 + v_3 = b + \frac{\mathrm{RT}}{p} \quad . \quad . \quad . \quad . \quad . \quad . \quad (\text{i.})$$

$$v_1v_2 + v_2v_3 + v_3v_1 = \frac{a}{p} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\text{ii.})$$

$$v_1v_2v_3 = \frac{ab}{p} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\text{iii.})$$

Now, for any definite value of T less than the critical temperature, these equations give, when we put p equal to the maximum vapour-pressure corresponding to this temperature, three values, v_1, v_2, v_3, two of which (say v_1 and v_2) denote the volumes of unit mass of the substance in the states of saturated vapour and "saturated" liquid at this temperature. Accordingly, $\frac{1}{v_1}$ and $\frac{1}{v_2}$ denote the densities of the substance in these states, and the law of Cailletet and Mathias, above referred to, enunciates that the arithmetic mean of these densities can be very fairly represented as a linear function of the temperature. Therefore we can write:—

$$\frac{v_1 + v_2}{v_1v_2} = \phi\mathrm{T} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\text{iv.})$$

where ϕ denotes a linear function, whose two constants are known.

Eliminating v_1, v_2, and v_3 from the four equations (i.), (ii.), (iii.) and (iv.), we readily obtain:—

$$p = \frac{\mathrm{RT}(1 - b\phi\mathrm{T}) - a\phi\mathrm{T}(1 - b\phi\mathrm{T})^2}{b^2\phi\mathrm{T}} \quad . \quad . \quad . \quad (\text{v.})$$

This result simply amounts to the following:—

If we fix the temperature T of a vapour, then the maximum vapour-pressure at this temperature is completely determined, *i.e.*

$$p = \mathrm{F(T)}.$$

Similarly the sum of the densities of saturated vapour and liquid in contact with it is determinate if T is fixed, and thus

$$\frac{1}{v_1} + \frac{1}{v_2} = \phi(\mathrm{T}).$$

Equation (v.) shows that the former function is known if the latter be known, and as Cailletet and Mathias have shown that the latter is very approximately linear, we can give the form of F(T).

This result, however, is not of any practical use unless the equation of state does really apply with good approximation to the region of liquid and vapour. F. G. DONNAN.

Holywood, Co. Down.

Colours of Mother-of-Pearl.

IN numerous text-books the colours of mother-of-pearl are included amongst phenomena of colour produced by striated surfaces, and though it is conceded that only a part of the colour is due to this cause, that part is generally assumed to be, at any rate, an appreciable quantity. Experiment will show, however, that such is not the case. When the colour produced by the striations is viewed in an impression of the pearl on sealing wax or gelatine it is visible, though it is totally different in character from the iridescence of the pearl itself, in which the tiny contribution of colour from the striations is completely overpowered by that due to another cause. In white mother-of-pearl the striations are often as close together as in coloured varieties, and at certain angles, when viewed by light from a defined source, there is a little colour visible in the white specimens; just so much, and no more, is contributed by the striations of the coloured specimens, as may be shown by viewing a piece under the surface of water, when the effect of the striations is necessarily abolished, though the iridescence is not at all appreciably diminished. The whiteness of some varieties must be attributed to a different thickness or greater opacity of the laminæ. It is

these laminæ which, acting as "films," give rise to all the colour of nacre, practically; and the phenomenon should be included amongst those of colours from "films," and not from "striated surfaces," the latter being merely incidental, and for all practical purposes contributing nothing to the effect.

C. E. Benham.

A RATIONAL CURE FOR SNAKE-BITE.

When it was established beyond dispute or cavil that the serum obtained from animals, immunised against bacterial infections and intoxications, possesses in a marked degree antitoxic powers (as distinguished from antibiotic powers) and that such serum when mixed in a test-tube with the bacterial poison in question will, so to speak, neutralise the toxic effects of such poison, however deadly, it was merely a question of time, opportunity, and patience that attempts would be made to extend the principle of serum-immunisation to other, *i.e.* non-bacterial, poisons. Ehrlich was the first to show us the way. He gradually accustomed animals to withstand comparatively large doses of abrine, ricine, and robine, three vegetable toxines, all belonging to the group of proteines, reacting as albumoses or globulines. In that manner he produced in the animals a relative immunity, or perhaps, more correctly, a tolerance. He found that though subcutaneous inoculations lead to better results, that this immunity can be brought about also by feeding. In whatever way the animal is prepared, its serum eventually acquires specific antitoxic, immunising, and curative properties. It was thus demonstrated that the wonderful discovery of Behring and Kitasato—for which Behring, however, claims the sole credit—has a scope much wider than at first was dreamt of. Behring himself, to begin with, explained the action of the serum as antibiotic or germicidal; but it soon became evident that, though when injected into the animal body it causes the destruction and death of the infective pathogenic organisms, nevertheless its chief action is "vitally" antitoxic. For working with the tetanus toxine alone, separated from the bacilli which produced it, its deadly effects can be readily neutralised by a few cubic centimetres of a powerful serum. And if we remember that ·23 milligram of tetano-toxine would represent the fatal dose for a human being weighing 70 kilogrammes, then we can get an idea as to what extraordinary changes must have been produced in the serum, or rather in the blood and tissues, of the immunised animal, to enable its serum instantaneously to remove the lethal effect of the toxine. The only poison comparable to tetano-toxine in virulence and rapidity of action is cobra poison, and it also resembles chemically the bacterial toxines, reacting as an albumose, though for the sake of accuracy it must be mentioned, that the poison of tetanus has been clearly shown by Brieger, Cohn, and Sidney Martin not to be an albuminous body, and that possibly most of the bacterial toxines may turn out not to be albuminous substances. Still, so far as our present knowledge reaches, cobra poison and other snake venoms are chemically closely allied and analogous to the "toxalbumins" of bacteria.

It had also been demonstrated by several observers,[1] that by means of oft-repeated injections of small sub-lethal doses of snake poison (rattlesnake, cobra, or viper venom) the resistance of an animal against the poison may gradually be increased considerably, it may be rendered "giftfest," to borrow a German expression. In fact, all the methods used for inducing a tolerance against tetanus poison can be shown to work in the case of cobra poison (this is the poison generally employed). That Calmette, whose work in this line follows directly that of Sewall's and of the writer of this article, has shown that a so-called immunity can also be produced by gradually increasing injections of poison attenuated by heat, iodine, trichloride of iodine, hypochloride of calcium, &c.; in fact, the analogy is complete. From this stage, at which others had already arrived, Calmette went ahead with Phisalix and Bertrand. Having previously attempted both to prevent and to cure the effects of inoculation with cobra poison by means of chloride of gold—wherein, however, as shown by the writer,[1] he failed—he directed his attention at once to the serum of immunised animals, and in February 1894 he showed, before the Société de Biologie, that on mixing cobra or viper venom with small quantities of serum obtained from an immunised rabbit the deadly effect of the venom disappears, a fact at once confirmed by independent observations of Phisalix and Bertrand. In May 1894 and in April 1895, Calmette published two concise papers in Pasteur's *Annales*, containing a full account of his results. These, briefly summarised, are as follows: (1) The serum of an animal immunised against snake poison (he used poisons of the following snakes: *Naja tripudians and haje, Crotalus durissus, Bothrops lanceolatus, Cerastes, Pseudechis porphyriacus, Hoplocephalus curtis and variegatus, Acanthopis antarctica, Trimeresurus viridis*) possesses properties similar to those which the serum of animals immunised against tetanus and diphtheria possesses. (2) The serum of a rabbit immunised against cobra or viper venom acts equally well against any of the other poisons, *i.e.* there is no specificity of action, as judged by the species of snake. (3) The serum possesses not only neutralising properties when mixed with the venom in a test-tube, but possesses also marked immunising and curative properties, *i.e.* poison injected after previous serum administration becomes powerless, and serum injected after previous poison administration neutralises the effects of the poison in the animal body, even after the symptoms of intoxication have already set in. Naturally the effect depends on the degree of immunity of the serum giver and on the proportionate amount of serum used. (4) The immunising effect produced by serum injections is not so lasting as that produced by direct injections of the poison, *i.e.* serum injections are incapable of rendering animals "giftfest." Calmette alludes to other matters, but since these are of secondary importance and still debatable, and not directly related to the subject of this article, we must pass them over. There is, however, one point which must be mentioned, since it is one affecting the whole principle of serum immunisation. He states that he has succeeded in producing a "Giftfestigkeit" by means of repeated intravenous injections of hypochloride of calcium, and that the serum of such "chlorinated" animals will neutralise, in the test-tube at least, the effects of cobra poison. Roux elsewhere mentions[2] that the serum of animals immunised against tetanus or rabies is capable of neutralising snake venom and of protecting other animals against subsequent intoxication with cobra poison, and that rabbits vaccinated against rabies can withstand four to five times the lethal dose of cobra venom; and also that abrine serum will counteract the effects of cobra poison, and cobra serum those of abrine. Calmette goes so far as to say that an animal vaccinated against abrine may acquire a relative immunity against diphtheria, ricine, and anthrax. If this be so, we shall have to modify our views as to the specific action of antitoxic serum, *i.e.* the first principle of serum therapeutics. We require a number of control observations before we can accept these remarkable statements; partial contradiction they have already received from Germany,[3] and the

[1] *Lancet*, June 11, 1892. The uselessness of strychnine was previously demonstrated by the writer in his paper in the *Journal of Physiology*.

[2] *Annales de l'Inst. Past.* 1894, No. 11, p. 722.

[3] Ehrlich emphatically denies any such vicarious counteraction with regard to abrine and ricine (cf. *Deutsche Med. Wochenschrift*, vol. xvii. No. 44, p. 1218).

writer's own experiments, so far at least, do not lend much support to them. So long, however, as the whole question of this new treatment, striking though it is in its results, is still a mystery to us, we cannot afford to push aside observations because they seem improbable, or because they are contradictory.

Calmette asserts also that the fresh serum of *Naja tripudians* (a species of cobra) possesses to some degree at least immunising properties, and, as we shall see, Fraser[1] bears him out in this, by stating that fresh serum of poisonous snakes possesses strong antitoxic and protective properties, not only against their own venom, but also against that of other species. D. D. Cunningham[2] and the writer,[3] however, in India, invariably failed to obtain antitoxic or immunising effects with cobra blood or serum, although the writer succeeded in keeping the effects of cobra poison in abeyance by means of the blood (or serum) of the *Varanus Bengalensis*, a large lizard which is naturally strongly resistant against cobra poison.

These are the chief results obtained by Calmette, and knowing the difficulties of working with such deadly poison as cobra poison venom is, and the innumerable failures which accompany it, the writer is able to appreciate the success of the French author, all the more since he himself failed while working on the same lines where to succeed seemed simply a matter of course. Recently these French observations have received entire confirmation in their leading points by Prof. Fraser of Edinburgh, and the writer may be forgiven for stating here that though he took up the control of Calmette's work with strong bias against the latter, he felt himself forced, already before Fraser's communications appeared, to acknowledge the correctness of the work done at Pasteur's Institute, so far as the antitoxic and immunising properties against cobra poison of serum obtained from animals treated with that poison are concerned. He has not, however, convinced himself that hypochloride of calcium can immunise animals, or lead to the formation of an antitoxic serum. Fraser's contributions, though merely confirmatory, are of great importance, since they contain unquestionable proof of the truth of what must have appeared to all, except a few shrieking "zoophilists," to be striking and surprising revelations. The credit, however, of the discovery of a cure for snake-bite in the laboratory at least belongs solely to France. Having discussed Calmette's work more fully, we can speak of Fraser's experiments in a few words; but thereby we do not wish to detract in any way from the merit which characterises his researches.

Fraser[4] worked with venom obtained from the Indian cobra, three species of rattlesnakes (*Crotalus horridus*, *C. adamanteus*, and *C. durissus*), the copper-head (*Trigonocephalus contortrix*), the Australian black and brown snakes, and an unidentified *Diemenia* (*Pseudechis porphyriacus* and *Diemenia superciliosa*), the African puff-adder, night adder, yellow cobra, and "rinkas" (*Vipera arietans*, *Aspidelaps lubricus*, *Naja haje*, *Sepedon hæmachates*). He immunised his animals by the usual method of minimal subcutaneous inoculations, or by feeding, against the venoms of some of the snakes mentioned, and then established (*a*) the strong specific antidotal properties of the serum of these vaccinated animals against the poison with which they had been vaccinated, and (*b*) the vicarious antidotal properties against the other poisons. This serum he obtained in a dry, pulverisable condition without any appreciable loss of antidotal power; but we can hardly forgive him the hybrid and barbaric name "antivenene" which he applies to it. He confirms Calmette's results in almost every point, so that there is no longer any doubt left as to possibility of a successful cure against snakebite, especially as, by both observers, the curative injection was shown to be efficacious when the symptoms of intoxication had already set in, and as the experimental animals used were highly susceptible to the poisonous action of serpents' venoms, while man is weight for weight much less sensitive than a guinea-pig or a rabbit. True, Fraser has generally worked with comparatively small lethal doses; this possible objection is, however, met by Calmette's results, which were obtained with much larger doses, and which therefore allow us to judge favourably of the practical application of the serum treatment. The final verdict must, of course, depend on the success or failure following the use of the serum in cases of snake-bite, and it must be remembered that, striking though our laboratory results are with tetanus antitoxine, so far the success obtained with acute cases of tetanus in man is disappointingly small, as the writer has shown elsewhere.[1] Yet here we have a rational method of treatment, and the promise of almost certain success; we must now look for facilities and opportunities of trying the cure. In France they have already begun to manufacture this antitoxic serum in larger quantity, and Calmette writes that he has immunised a horse, and is ready to supply the remedy; and Fraser also has larger animals under treatment. No doubt India will not delay in carrying out the necessary arrangements for procuring what, after all, will be an imperial benefit.

The vicarious action of the immunising venom-serum is surprising, and may find an explanation in the similarity of the physiological action of the various poisons used. They are all poisons which cause death by acting on the central nervous system, especially the medulla, the animal dying from respiratory failure with salivation, retching, &c. And it is quite possible that chemically similar poisons which, according to their action on the animal body, belong to one physiological group, have the same antidote. It would therefore be interesting to test the antitoxic cobra-serum on the poison of the Daboia, which, according to Wall, Cunningham, and others, differs essentially in its physiological action; for whereas cobra, crotalus, and viper venoms are paralysing, medullary poisons, the poison of Russell's viper produces very varying symptoms, in some cases convulsions, in others paralysis and asphyxia, in yet others violent convulsions followed by paralysis. Daboia venom undoubtedly contains a substance capable of producing the most violent convulsions, especially in birds, their occurrence depending on the size of the animal and on the amount of poison injected. It would indeed be more than a surprising revelation, if a serum which is capable of acting as an antidote to a paralysing toxine were also capable of neutralising the effects of a toxine of opposite physiological action.

The vicarious antidotal action of venom-serum must appear all the stranger and more contradictory if we remember that not all poisonous snakes are "giftfest" against the poisons of other different species. Waddell[2] has shown that the venom is neither a poison to the snake itself nor to members of its own species, but that cobra poison is fatal to some, if not perhaps to all, poisonous snakes. It will certainly kill the *Trimeresurus erythrurus*, and in the writer's experience also the crotalus, while according to Fayrer the *Bungarus* readily falls a victim to the bite of a cobra. This being so, why should the antitoxic serum of an animal immunised against cobra-poison be active against rattlesnake venom, when in an experiment recently performed by the writer, a strong and healthy crotalus succumbed to five milligrammes of cobra venom? Lastly some writers, Fraser included, assume that the immunity of poisonous snakes against their own

poison depends on self-immunisation, called forth by swallowing their own venom, or by repeatedly inoculating themselves. This is highly improbable, if we remember that some of the innocent snakes are very resistant against cobra poison, as, *e.g.*, the *Ptyas mucosus* and the *Tropidonotus natrix*, and also that, as the writer has shown, the *Varanus Bengalensis* is possessed of a marked tolerance, and that, according to Fayrer, other species of *Varanus* survive the bite of a cobra 24 to 48 hours. Jourdain further gives a list of four innocent snakes which are immune against viper venom. In what manner are we to account for this immunity? Interesting observations on the poisonous nature of serum of innocent and poisonous snakes are also found in Calmette's paper of April 1895, which, while rendering Fraser's theory still more improbable, do not assist us in clearing up the mystery. The explanation must be left to future researches; for the present we must be thankful for the promise which the researches of Calmette and Fraser have given us, of allaying an almost national calamity.

A. A. K.

SCIENTIFIC KNOWLEDGE OF THE ANCIENT CHINESE.

THE question of China has been so much to the front lately, that an article which appeared in one of the August numbers of the *Revue Scientifique*, on the knowledge of science possessed by the Chinese, seems very *à propos*. It cannot be denied that the Chinese of the present day have very elementary ideas on any branch of science. This however, was not so formerly.

In early times, as far back even as 2000 B.C., we find that science in China had reached a fairly advanced stage. The Chinese possessed undoubtedly a great knowledge of astronomy; inscriptions have been found which prove this. In the "Chou-King," a book of records, we read that Emperor Yao, who reigned 2357 B.C., did much to advance the study of this science. He ordered his astronomers to observe the movements of the sun, moon and stars, and showed them how to find out the commencement of the four seasons by means of certain stars. We read also that he told them that a year consisted of a little less than 366 days, and as he divided the year into lunar months, he taught them the years in which the additional lunar month ought to be included. It is also known that the Chinese had the annual calendar, that they observed the planets Mercury, Venus, Mars, Jupiter, Saturn, and were able to calculate eclipses, and knew the difference between the equator and the ecliptic. It is quite probable that the ecliptic was not known of before the Mussulmans occupied the Mathematical Tribunal, which they held for three centuries.

We see, therefore, that the knowledge of astronomy was very extensive. With regard to the meridian, it was apparently unknown to them. M. Chavannes, who is at present Professor of Chinese at the College of France, says that it is not mentioned in any astronomical book. As substitute a certain star was observed at the same hour, according to the times of the year, note being taken of its positions with regard to the horizon.

Astronomy has always been closely connected with astrology. By means of astronomy the time was ascertained for the numerous public ceremonies recorded in the Imperial calendar; it likewise regulated the affairs of the Government. But the calendar has long since ceased to be used for this latter purpose, and the majority of the Chinese population merely look upon it as a means of continuing the mysterious ceremonies and oracles connected with the different positions of the planets. It is ordered in the "Collection of the Laws," that at each eclipse, ceremonies should be gone through to succour the eclipsed sun or moon. At this time therefore, an alarm is sounded on the drums, the mandarins arrive armed, utter many objurgations, and thus deliver the endangered bodies.

In the seventeenth century, certain Jesuit missionaries arrived in China. On seeing the low state into which the Mathematical Tribunal had fallen, they offered to help it. They found an observatory containing many instruments, which shows plainly that this branch of science had at one time reached an advanced stage. This decay of science is not to be wondered at when we remember that twenty-two dynasties were brought on the throne by actual revolutions. Nor is this decay confined to astronomy. According to the ancient books and traditions, we find that various branches of science had reached a high degree of culture.

The Emperor Kang-hi, who reigned in the seventeenth century, had a great love of study himself, and endeavoured to advance the general education in China. The Jesuit missionaries instructed him in geometry and physics. He translated some text-books into Chinese.

The Chinese have generally been credited with the invention of gunpowder. A certain document has been found, however, by Archimandrite Palladius, a Russian sinologue, stating that in the ninth century a Persian regiment, under the Chinese sovereign, made known a material similar to wild fire, which was afterwards used for fireworks.

Apparently, chemistry has never been studied, unless by a certain sect, the Tao-tse, who spent all their time endeavouring to discover the philosopher's stone and the elixir of life.

The Chinese have not a great knowledge of geology. The mines have been worked without any machinery, and are not very deep, therefore fire-damp has rarely been the cause of destruction. Coal was extracted at as early time as 200 B.C. in the dynasty of Han. Although the mode of extraction was very primitive, enough was obtained to satisfy all wants.

About 1861 the Government handed the exploration of the mines over to American prospectors. The work, lasting from 1862-64, was directed by Prof. Pumpelli, who at its termination sent the Emperor a report and a map of the coal-fields. The Smithsonian Institute of Washington have had these documents published; they have also appeared in the diplomatic correspondence of the United States (1864). Later on, Baron de Richtofen did similar work, and found that the coal-fields in China are even more extensive than those in North America.

Research work has not been carried far in natural science. In zoology their classifications are quite wrong. The drawings in zoological and botanical books can often scarcely be recognised. Their most ancient work on botany dates from 2700 B.C., and is a treatise written by the Emperor Shen-nung; it is merely enumerative. Another work, the "Rh-ya," dates from 1200 B.C., and shows signs of progress. The "Pen-tsao," an encyclopedia, is, according to M. Bretschneider, of little value.

This Russian investigator speaks of the Chinese as follows: "It is an undeniable fact that the Chinese do not know how to observe, and have no regard for truth; their style is negligent, full of ambiguities and contradictions teeming with marvellous and childish digressions."

However, in a more recent communication, M. Bretschneider retracts his words, and says that it is more that the Chinese will not observe, than that they cannot, for Lichi-Tchen, author of several interesting pamphlets, brings forward many facts concerning cultivated plants.

With regard to medical science, it is very elementary. Occasionally here and there a successful doctor is to be found. This lack of knowledge is not to be wondered at, for Buddhism forbids dissection of bodies. In the temple of Confucius a bronze figure is to be found, on which all the different parts are marked where the surgical needle

may be applied. This needle is practically the only instrument used in the profession.

The height of civilisation in China was reached at the end of the reign of Kang-hi. The gradual decline is supposed to have commenced with the Tartar domination.

THE FLORA OF THE GALAPAGOS ISLANDS.

DR. G. BAUR'S theory of the origin of the Galapagos Islands is too well known to need explanation here: yet it may be briefly designated the theory of subsidence. He argues that the islands were formerly connected with each other, and at an earlier period with the American continent. It is also almost needless to say that this theory has met with an exceedingly hostile reception; few indeed accepting it, even as restricted to a former union of the islands themselves. The publication of an account of the botanical collections[1] affords an opportunity of examining this theory from a botanical standpoint. For the purposes of the "Botany" of the *Challenger* Expedition, and ever since the publication of that work, I have collected all the data coming under my notice bearing on the dispersal of plants to considerable distances by wind, water, birds or other creatures excepting human. The evidence thus collected sufficiently accounts for the vegetation of low coral islands, and the littoral vegetation of widely separated countries; but it in no way helps to explain the vegetation of the enormously distant islands of the Antarctic seas, for example, or that of the islands of the Galapagos group, to give another instance.

But these are not parallel cases; they are the two extremes in the amount of differentiation in connection with isolation.

The biological phenomena of the Galapagos Islands left a deeper impression, probably, on the mind of Darwin than those of any other part of the world he visited, and doubtless had much to do with his later conception of the origin of species. The fact on which he laid special stress was that the genera, to a very great extent, were the same in all the islands, and the species different in each island. Dr. Baur's much more extensive zoological and botanical collections and observations confirm and emphasise the correctness of the view of his illustrious predecessor of fifty years ago. Darwin specially refers to the existence of different species or races of tortoises and mocking-thrushes in many of the islands; and Baur's examination of the lizards of the genus *Tropidurus*, from twelve of the islands, reveals the same condition of things. The botanists bring forward *Euphorbia viminea* in illustration of this phenomenon. This species was described by Sir Joseph Hooker from a single specimen collected by Macrae in Albemarle Island, and the author remarks that he "knew of no species with which to compare this highly curious one." Dr. Baur collected it extensively in eight of the islands, and the specimens from almost every one of them exhibit distinct racial characteristics. *Acalypha*, a genus of the same natural order, presents somewhat more pronounced variation in the different islands, which some botanists regard as of specific value; other botanists as of varietal value only. Whatever status we give these forms, the flora as a whole is a most instructive and convincing illustration of evolution.

A remarkable peculiarity of the Galapagos flora, as an insular flora, is the almost total absence of endemic genera, for the two or three genera of the Compositæ restricted to the islands are so closely allied to American genera as hardly to count as distinct. Indeed the whole flora is so thoroughly American that, apart from geological difficulties, it might be regarded as a differentiated remnant thereof, rather than derived therefrom, after the supposed elevation of the islands. Analogous conditions and phenomena are repeated in the deep valleys of the great mountain chains of northern India and western China, where, in neighbouring valleys, the genera are to a great extent the same and the species different.

Returning to Dr. Baur's extensive botanical collections from the Galapagos, it may be mentioned that they yielded about a dozen new species belonging to the predominating genera.

Looking at the composition of the Galapagos flora, especially with an eye to the probabilities of the transport of the seeds of its constituents, combined with present conditions, Dr. Baur's theory seems deserving of more serious consideration than it has hitherto received. My very slender knowledge of geology alone prevents me from taking up a more decided position.

W. BOTTING HEMSLEY.

[1] B. L. Robinson and J. M. Greenman, in *American Journal of Science*, vol. l. pp. 135-149.
N.B.—Dr. G. Baur was attached to the United States Fish Commission steamer *Albatross*, and spent nearly three months in the islands, from June 10 to September 6, 1891.

THE LATE PROFESSOR HOPPE-SEYLER.[1]

II.

Hoppe-Seyler's Work in Berlin, 1850 54 *and* 1856–61.

IT has already been stated that Hoppe selected as the subject of his inaugural dissertation some observations on the structure of cartilage and on chondrin.[2] Chondrin had been first separated and examined by Johannes Müller,[3] and afterwards by Mulder and Donders. Pursuing his study of the chemical reactions of the so-called chondrin, Hoppe in 1852[4] described its lævo-rotatory property, and showed that when decomposed by long boiling with dilute mineral acids it yields leucine, but neither glycocine nor tyrosine. Still directing his attention to the connective tissues, Hoppe in the following year published a valuable and interesting paper[5] on the structural elements of cartilage, bone, and tooth. Virchow had shown[6] the possibility of isolating the so-called bone corpuscles. Hoppe now alleged facts which seemed to prove that the lacunæ and canaliculi of bone are lined by a tissue resembling elastic tissue, and are left surrounding the bone cells when decalcified bone is boiled in a Papin's digester. Extending his investigation to tooth, Hoppe studied the chemistry of the organic basis of dentine, and isolated the "dentinal sheaths," which he showed to correspond structurally and chemically to the more internal portion of the ground substance of bone, which may be separated as a distinct investment bordering the lacunæ, canaliculi, and Haversian canals. There can be no question of the important bearing which these early histologic-chemical researches had upon the development of our knowledge of the relations and affinities of the connective tissues: attention has been drawn to them for this reason, as well as because they differed somewhat in their scope and method from the work with which Hoppe afterwards mainly busied himself.

Passing over three interesting papers on auscultation[7] and communications of minor importance on chemical

[1] In the fragmentary notes which follow, I do not pretend to give a complete or entirely consecutive account of Hoppe-Seyler's labours; my object is to draw attention to some of the principal results of his life-work, and to indicate in this way his position among those who, during the last half-century, have contributed to the advancement of biological science.—A. G.

questions relating to physiology and pathology, we come to the first in the long series of valuable contributions which Hoppe made to the physiological chemistry of the blood. This short paper of only two pages was published in 1857, after his return to Berlin, and consisted of a preliminary communication on the action of carbonic oxide on the blood.[1] In this paper he announced that carbonic oxide so affects the colouring-matter (at that time designated Hämatoglobulin by Hoppe) as to render it incapable of fulfilling the function, so important for the blood as well as for the whole organism, of acting as the carrier of oxygen. Simultaneously and independently, Claude Bernard[2] had observed the same facts as Hoppe, and had shown, in addition, that when carbonic oxide acts upon blood it is absorbed and displaces oxygen. Although his analytical data did not bear out the assertion, Claude Bernard stated that for each volume of oxygen displaced one volume of carbonic oxide is absorbed, a relation which was afterwards shown to be actually correct by the fine investigation of Lothar Meyer.[3] As will be afterwards stated, it was, however, Hoppe-Seyler who, in 1865, after Stokes' beautiful researches on the reduction of oxy-hæmoglobin, furnished the complete explanation of the way in which carbonic oxide exerts its action on the blood and its colouring-matter, and placed in the hands of the medical jurist a method of distinguishing between blood which has been rendered florid by carbonic oxide and blood which owes its red arterial colour to oxygen.

The year 1857 witnessed also the publication of the first[4] of a series of researches on the property which many of the proximate principles of the body possess of rotating the plane of polarisation. Biot had discovered that albumin rotates the plane of polarisation to the left, and Bouchardat and A. Becquerel had endeavoured, but without success, to base upon this discovery a method for the quantitative estimation of albumin. In his first paper Hoppe showed (1) that, as was to be predicted, the rotation produced by a solution of albumin was strictly proportional to the amount of albumin in solution, and to the thickness of the stratum traversed by the light; (2) that albumin existing in a state of solution in a liquid rotates the plane of polarisation of light almost exactly as much to the left as an equal percentage of grape sugar rotates it to the right. In the same year (1857) and the year following, Hoppe published other papers on the rotatory properties of other organic proximate principles of the animal body.[5]

With his hands full of original work, with the chemical laboratory of the Pathological Institute to direct, busily helping the students who were attracted to work under a teacher full of enthusiasm and ability, Hoppe yet found time to publish, in 1858, the first edition of his "Handbook of Physiologico-Chemical and Pathologico-Chemical Analysis."[6] The only work at that time in existence which fulfilled the same object was the very useful work of Gorup-Besanez, of which the first edition appeared in 1850, the second in 1854,[7] and the third and last in 1871. Hoppe-Seyler's book was written on lines essentially the same, but was distinguished by containing many new methods, the results of the original researches of its author; as, for example, on the rotatory properties of various origanic bodies, on the polarimetric estimation of albumin and milk-sugar, on the colorimetric estimation of the blood-colouring matter, on new methods of blood analysis, &c. Personally, the writer is greatly indebted to the first and the subsequent editions of Hoppe-Seyler's work, and in saying that it has exerted a powerful and useful influence in diffusing a knowledge of the best methods of practical work throughout the laboratories where researches in physiological chemistry are pursued, he is only expressing an opinion which he believes to be shared by all who are best qualified to judge. In spite of a decided narrowness, amounting at times to unfairness, which asserts itself in nearly all Hoppe-Seyler's writings, and which caused him to attach undue importance to his own work and that of his own pupils, and which explains some unfortunate omissions and deficiencies, the "Handbook" remains the recognised practical work consulted by the student of physiological chemistry. The sixth, and last, edition of the book,[1] edited jointly by Hoppe-Seyler and his pupil Dr. Thierfelder, appeared early in 1893.

Hoppe-Seyler's Work in Tübingen, 1861-72.

With his appointment as ordinary Professor of Applied Chemistry in the University of Tübingen commenced the most prolific period of Hoppe-Seyler's scientific life, during which he contributed to science his researches on hæmoglobin and its derivatives—researches which, with the work of Stokes, Claude Bernard, Pflüger, Ludwig and his school, have furnished us with the greater part of the knowledge which we at present possess concerning the chemistry of the blood-colouring matter and the part which it plays in respiration. At Tübingen, Hoppe, then in the very prime of life, surrounded by pupils, amongst whom were Diakonow, Dybkowsky, Miescher, Parke, and Salkowski, showed much more clearly than was possible in the position which he occupied in Berlin, his capacity to be the head of a school—that is, his power of inducing men to work out his own ideas, and of animating them with the desire to advance science by their own researches.

It was in 1862 that appeared Hoppe's short but epoch-marking paper "On the behaviour of the blood-colouring matter in the spectrum of sunlight."[2] Through the researches of Brewster and Herschel, the fact that absorption bands occurred in the spectrum of light which had been passed through certain coloured gases, vapours, and diluted coloured solutions had become known, and the absorption spectra of indigo and chlorophyll had been described. The discovery of the wonderfully characteristic absorption spectrum of blood at once enabled Hoppe to assert that hæmatin, which had up to that time been by many considered the true blood-colouring matter, did not exist preformed in the blood corpuscles, but that it is a product of decomposition of the true blood-colouring matter which is the cause of the absorption bands which he had discovered, and which, under the influence of heat, acids, &c., splits up into hæmatin and an albuminous substance. Without doubt, added Hoppe, the true blood-colouring matter is the body which forms the blood crystals of Funcke, and these crystals are not, as Lehmann had erroneously supposed, composed of a colourless albuminous *hæmatocrystalline* stained with hæmatin.

There can be no question that Hoppe at once appreciated the immense value of the information which

1 "Handbuch der Physiologisch- und Pathologisch-Chemischen Analyse für Aerzte und Studirende, von Felix Hoppe-Seyler. Sechste Auflage neu bearbeitet von F. Hoppe-Seyler, Professor in Strassburg, und H. Thierfelder, Privat-docent in Berlin. (Berlin, Verlag von Aug. Hirschwald, 1893.)

2 Prof. Felix Hoppe in Tübingen, "Ueber das Verhalten des Blutfarbstoffes im Spectrum des Sonnenlichtes," Virchow's *Archiv*, vol. xxiii. (1862), pp. 446-449.

he had acquired by his study of the spectrum of blood, though the full light which it was destined to throw on the function of the blood-colouring matter was only recognised when Stokes published his paper "On the Reduction and Oxidation of the Colouring-matter of the Blood." Having described the beautiful experiments which he had performed after becoming acquainted with Hoppe's paper on the blood spectrum, Stokes stated the conclusions, which might legitimately be drawn from them in the following words: "We may infer from the facts above mentioned that the colouring-matter of blood, like indigo, is capable of existing in two states of oxidation, distinguishable by a difference of colour and a fundamental difference in the action of the spectrum. It may be made to pass from the more to the less oxidised state by the action of suitable reducing agents, and recovers its oxygen by absorption from the air."[1]

The new facts acquired by the combined use of chemical and optical methods at once explained a large number of facts. Hoppe-Seyler showed that carbonic oxide blood was distinguished from normal blood in being unacted upon by reducing agents, and thus placed a valuable test in the hands of the medical jurist called upon to investigate cases of death by charcoal fumes.[2] The explanation of the facts discovered by Claude Bernard and by Lothar Meyer was obvious—to wit, that carbonic oxide forms a compound with the blood-colouring matter, more stable than the oxygen compound, and in which apparently one molecule of CO has replaced O_2.

With the resources of spectrum analysis to aid him, Hoppe now devoted himself with energy to the investigation of the blood-colouring matter (which he named Haemoglobin[3]), showing how to separate and purify it by repeated crystallisation, determining its composition, studying personally, and, with the aid of his pupil Dybkowsky, its combinations with oxygen and with carbonic oxide, examining its products of decomposition, and showing its probable connections with certain other animal colouring matters.[4]

It would be impossible in this place to comment in detail on all Hoppe-Seyler's contributions to the chemistry of the blood-colouring matter; these constitute his highest claim to distinction, and will ever cause him to be remembered as having contributed most largely to our knowledge of the manner in which the respiratory exchanges of animals are effected.

Until he removed from Berlin to Tübingen, and for some time after, Hoppe-Seyler published his researches for the most part in Virchow's *Archiv*, some of his papers appearing, however, in Fresenius' *Zeitschrift*, in the *Annalen d. Chemie und Pharmacie*, and in the *Berichte* of the Chemical Society of Berlin. In 1866, however, he commenced the publication of the collected papers issuing from his laboratory, under the title of "Med.-Chemische Untersuchungen."[5] Four parts of this publication appeared, the last in 1871.

Hoppe-Seyler's Work in Strasburg, 1872–1895.

A proper estimate of Hoppe-Seyler's work would necessitate a careful review of the fine researches published by his pupils, for there can be no doubt that in his case, as in that of many of the most distinguished scientific men of Germany, the work of the master has often been credited to the pupil under whose name it has appeared. It is obvious, however, that it would be impossible, within the limits of such an article as the present one, to give an account, however brief, of the succession of valuable papers which issued from the new Physiologico-Chemical Institute of Strasburg. Two events in Hoppe-Seyler's scientific life in Strasburg cannot, however, be passed over, viz. the publication of his "Text-Book of Physiological Chemistry," and the foundation of the *Zeitschrift für Physiologische Chemie*. The first part of the "Text-Book of Physiological Chemistry" appeared in 1877, the second in 1878, the third in 1879, and the fourth in 1881. This work is of interest as giving Hoppe-Seyler's views of the chemical processes of the body; yet it neither achieved nor merited great success. Devoted though he was to work by which he unquestionably did much to advance both physiology and pathology, Hoppe-Seyler was essentially a chemist rather than a biologist; and when, as in his systematic treatise, he left chemical, to speculate on biological, questions, his weak points became very obvious.

This account of Hoppe-Seyler's work must close with a reference to the great service which he rendered to our branch of science by founding, in 1877–78, the *Zeitschrift für Physiologische Chemie*. From the first number to the last this periodical has maintained a high standard, and, besides containing the results of all the work done in the Strasburg Laboratory, it has received contributions from nearly all the prominent workers in physiological chemistry. In succession to Hoppe-Seyler, Professors Baumann and Kossel are, it is understood, to be the future editors of this journal.

Arthur Gamgee.

NOTES.

We are informed that a biography of Prof. Huxley is being prepared by his son, Mr. Leonard Huxley, who will be greatly obliged if those who possess letters or other documents of interest will forward them to him at Charterhouse, Godalming. They will be carefully returned after being copied.

The Committee of the Pasteur Institute have appointed Dr. Duclaux, formerly sub-director, to succeed M. Pasteur as director, and Dr. Roux to be sub-director of the Institute.

We understand that the final interment of M. Pasteur in the Pasteur Institute will not take place on Friday, as had been intended, because the vault and part of the sculpture cannot be ready in time.

The centenary celebrations of the Institute of France commenced as we went to press yesterday, and will terminate on Saturday by a visit to the fine chateau of Chantilly, where the associates and members will be received by the Duc d'Aumale. An account of the foundation and membership of the Institute appeared in these columns a few weeks ago, and we hope to give in our next issue a full description of the ceremonies now taking place.

A bronze portrait bust of Dr. Robert Brown was unveiled on Friday in his native town, Montrose, Forfarshire at a reception held by the Provost, magistrates, and town council of Montrose. Beneath the bust is a tablet, with the following inscription:—"Robert Brown, D.C.L. Oxon., LL.D. Edinburgh, F.R.S. London, President of the Linnean Society, Member of the Institute of France. Born in this house 21st December, 1773; died in London 10th June, 1858. 'Botanicorum facile princeps,' Alex. Von Humboldt.'" A large number of distinguished botanists from all parts of the kingdom were present.

Mr. P. H. Lawrence, whose name will be remembered by some students of mineralogy, but more widely in legal circles, died a few days ago. We have also to record the death of Prof. E. W. Blake, until lately professor of physics in Brown University; of Dr. E. E. Rogers, instructor in chemistry at Harvard University; of Prof. A. Rydberg, the Swedish archæologist; of Mr. H. W. V. Stuart, who devoted much attention to the study of Egypt and its monuments; of Father Hirst, the author of numerous contributions to archæology; and of Dr. F. M. Stapff, the geologist, while prospecting for gold in East Africa.

The sixth Congress of Medicine was opened at Rome on Tuesday by Dr. Baccelli, Minister of Public Instruction.

In addition to the papers already notified in the usual way, to be read at the next meeting of the London Physical Society to-morrow, there will be read, if time permits, a paper "On the Magnetic Field of any Cylindrical Coil or Plane Circuit," by Mr. W. H. Everett.

The steamship *Windward*, which conveyed the members of the Jackson-Harmsworth Polar expedition to Franz Josef Land, arrived at Gravesend on Tuesday. It will be remembered that the *Windward* left the Thames in July 1894; she has brought back the records of the expedition from that date up to the beginning of July of this year. Mr. Jackson and his party remain in Franz Josef Land, and the vessel will return there, with stores, next June.

A Fine Art, Industrial and Maritime Exhibition will will be held in Cardiff in the spring and summer of 1896, under the patronage of Her Majesty the Queen. The general object of the exhibition is to illustrate the most recent progress in the sciences, arts, and manufactures, and not merely to be a popular show. The following is a list of the chief sections, and the number of square feet allotted to each:—Mining and mining appliances, 13,280; machinery, electricity, and local and general industries, 20,480; maritime, 8400; agriculture and horticulture, 7280; health, 5400; fine arts, 6600.

The annual exhibition of the South London Entomological and Natural History Society was held on Thursday last, and was much appreciated by the company who went to see the numerous interesting specimens arranged by the Committee. The Society has for its object the popularising of the study of natural history, and to promote this it holds bi-monthly meetings, at which papers are read, discussions take place, observations are communicated, and specimens shown and commented on. In the summer time field meetings are held for the purpose of collecting and observing, and periodical exhibitions are promoted. The Society's rooms are at Hibernia Chambers, London Bridge, where a large library and typical collections are kept for members' reference, as well as a lantern for demonstration purposes. At present the number of members is about two hundred. The Secretary is Mr. Stanley Edwards, Kidbrooke Lodge, Blackheath, S.E.

Mr. D. Pidgeon, Letherhead, sends us an account of a curious effect apparently produced by lightning in the early morning of September 7. In a cottage on Cherkley Court estate, three or four tumblers were left standing over-night, mouth upright, on a shelf affixed to the wall of a small pantry, and about twelve inches from the window, which was open. In the morning one of these tumblers was found to have a crack completely round it, so that a ring of glass, having an uniform width of half an inch, could be cleanly and easily detached. This hoop of glass has been preserved to be a witness to the vagaries of electrical discharge. There seems little doubt that electricity had to do with the formation of the crack, for large shrubs, just outside the open window near which the glasses stood, were found to have been damaged by the lightning. It would be interesting to know whether the glass was empty or not, or whether it was wet up to the level of the crack.

The Harveian Oration was delivered on Friday last, at the Royal College of Physicians, by Dr. W. S. Church, who took for his subject "Harvey and the Rise of Physiology in England." For 239 years, with but few intermissions, the College has met in obedience to Harvey's direction to commemorate its benefactors. After referring to the long list of these, Dr. Church remarked that during the present year the College had received the magnificent endowment of £3000 to establish a triennial prize for the furtherance of original research on the prevention and cure of tuberculosis, the donor being Dr. Hermann Weber, who, in instituting the prize, joined the name of the late Dr. E. A. Parkes with his own. After the delivery of the oration, the Baly medal was presented by the President, Sir Russell Reynolds, to Dr. W. H. Gaskell, F.R.S., of Cambridge. The medal is awarded biennially to some person who has distinguished himself in the science of physiology; it was founded in 1866 by Dr. F. D. Dyster, "In Memoriam Gulielmi Baly, M.D.," and amongst the names of those who have since received it are those of Claude Bernard, Carl Ludwig, Darwin, Owen, Kitchen-Parker, and Brown-Séquard.

In connection with the proposal to change the name of the Boulevard de Vaugirard to Boulevard Pasteur, the Paris correspondent of the *Chemist and Druggist* points out that a Rue Pasteur already exists, while twenty-one other streets of Paris have been named after chemists. Of these fourteen were of French nationality, and include Chevreul, Gay-Lussac, Lavoisier, Raspail, &c. Davy figures as the sole English chemist, and the only other foreigner is the Swede Berzélius. The names of seven botanists appear on street corners, amongst which are Dupetit-Thouars, Jussieu and Linné. Nicholas Flamel, writer and alchemist, who flourished in the second half of the fourteenth century, has the distinction of being the most remote name connected with sciences after which the Parisians have called a street. Thirty-nine thoroughfares take their names from doctors and surgeons; amongst these figure Jenner and Vesale, the Belgian anatomist, the only two foreign names. We commend the French custom to English and municipal authorities at a loss for suitable street names. It may be thought a doubtful honour to have one's name handed down to posterity in this manner, but the custom serves to show that men of science are remembered in France in little as well as in great things.

The following statistics, from the *Zoologist*, with reference to the progeny of a female Manx Cat and an ordinary Tom Cat, are interesting. The successive litters consisted of three on each occasion, and the distribution of tails is shown in the table:—

	No tails.	Half tails.	Full tails.
1st litter	3	0	0
2nd ,,	2	1	0
3rd ,,	1	2	0
4th ,,	0	2	1
5th ,,	0	1	2
6th ,,	0	0	3

The gradual elimination of the tailless condition characteristic of Manx cats is singular, and well worth putting on record.

Very little detailed information exists as to the effect of wind and atmospheric pressure on the tides around the British Isles, but it is to be hoped that the Committee appointed at the recent meeting of the British Association will succeed in eliciting sufficient trustworthy data to enable some general law to be deduced for the guidance of navigators. The Committee consists of Prof. Vernon Harcourt, Prof. Unwin, Mr. G. F.

Deacon, and Mr. W. H. Wheeler (Secretary); and as it is desirous of obtaining information from as many ports as possible, we are asked to make its existence known. A printed form, showing the manner in which it is proposed to collect the tidal statistics, will be sent to any one who will render assistance to the Committee, by Mr. W. H. Wheeler, Boston, Lincolnshire, who will also be glad to receive records of tides affected by gales.

In connection with the growth of orchids, writes Mr. J. H. Hart, in the October *Bulletin* of the Royal Botanic Gardens, Trinidad, it has been noticed that the presence of ants is apparently necessary to their maintaining a healthy condition; but whether this is in reality due to some action of the ant itself, or to some indirect cause, has not yet been proved, and investigations are needed to show what is the real influence the ant has upon the health of the plant. It has been suggested that the presence of stinging ants acts as a protection to the plants; but Mr. Hart is inclined to think, from recent investigations, that the benefit the ants confer on the plant are those of providing it with the mycelium of a fungus to cover its roots, which organism enables it to take up food which would be otherwise unattainable. It may be shown that the ants act as protectors to the plants, as well as providing them with a means of obtaining nutriment; but Mr. Hart believes it to be almost certain that the fungus which grows in the material they accumulate around the root plays a much more important part, by providing the plant with food material.

The first number of what promises to be a useful serial publication has just reached us from the U.S. Weather Bureau. The periodical has for its name *Climate and Health*: it is edited, under the direction of Prof. W. L. Moore, the new chief of the Weather Bureau, by Dr. W. F. R. Phillips, and it is devoted to climatology in relation to health and disease. Tables are given showing, for one hundred selected stations, statistical information relative to atmospheric pressure, temperature, humidity, precipitation, wind, and sunshine; the relative prevalence of certain diseases; and the mortality from different causes, in each State. In addition to these statistics, all of which refer to the conditions during July of this year, the new publication contains charts showing the average pressure departures from the normal, ranges of pressure, prevailing winds, and normal wind directions for each week in the month, and similar charts to exhibit graphically the absolute and relative data referring to temperature, humidity, and precipitation. There is also a chart for each week showing the total mortality by States, and representing diagrammatically the average climatological conditions so far as determined by the mean temperature and humidities and the total amount of precipitation. The general aim of the Weather Bureau in this new field of work is to collect the meteorological and hygienic statistics considered by medical climatologists of the greatest correlative importance, and to publish them in a useful and instructive form. By showing the statistics of mortality and morbidity side by side with those of climate, new information as to connections between sickness and weather changes will probably be discovered.

The *Psychological Review* for last month contains an interesting paper by Mr. R. Meade Bache, on "Reaction Time according to Race." He suggests that the higher intellectuality of civilised white races may have been gained at the sacrifice of quickness of response to sensory stimuli, and states that it is a matter of familiar observation that Negro children are quicker in their movements than the children of white folk. At his request Prof. Lightner Witmer made careful and exact observations on persons of the Caucasian, American Indian, and African (Negro) races. These are given in three tables. Taking response to auditory stimuli, for example, the order of quickness is (1) Indian, (2) African, (3) Caucasian, in the relation of 116·27 : 130 : 146·92; these being the reaction times in thousandths of a second. Although the numbers of individuals dealt with (not more than a dozen in each case) are small, the results are suggestive, and will no doubt lead to further investigation.

The attention of those who are interested in the question of the inheritance of acquired characters may be drawn to a paper which Prof. Mark Baldwin contributed to *Science* (August 23, 1895), under the title "Consciousness and Evolution." Prof. Baldwin fails to see any great amount of truth in the claims of Mr. Spencer that intellectual progress in the race requires the hereditary transmission of acquired increments in mental faculty, and adopts the view advanced by Weismann in 1889, and taken up more or less independently by Mr. Ritchie and Mr. Kidd, that social advance is rather by tradition than by hereditary transmission. "Man," said Prof. Weismann, "availing himself of tradition, is able, in every part of the intellectual domain, to seize upon the acquirements of his ancestors at the point where they left them, and to pursue them further, finally himself leaving the results of his own experience and the knowledge acquired during his lifetime to his descendants, that they may carry on the same process." Prof. Baldwin seems to have reached this view independently, and his paper is well worth reading.

Under the extraordinary heading of "The Chemical Theory of Freedom of Will," Dr. W. Ostwald makes, in the *Leipziger Berichte*, some suggestive speculations upon the mechanical theory of the universe. That all the phenomena of nature, organic as well as inorganic, should be ultimately of a purely mechanical character, is contradicted by the science of energy. The theorems of energetics give the conditions under which any event takes place: they indicate which out of all the possible courses it will follow, and to what state of equilibrium it tends. All this does not involve the element of time, except in the case of kinetic energy. In the equations representing mechanical processes, time may be put as positive or negative without rendering them invalid. In other words, all purely mechanical processes are reversible, while natural processes are not. They have a forward and a backward aspect. Now there are processes in nature in which an agent influences the time during which a certain event takes place, without being itself affected in any way. This happens in all cases of catalysis, and the laws of catalytic action are as yet only very imperfectly understood. It is known, however, that the acceleration of the process is proportioned to the concentration of the catalyser. May not the human mind, the author argues, act upon matter somewhat in the manner of a catalyser, accelerating the chemical and mechanical processes associated with psychical activity without any expenditure of energy? This may be worth considering. But it must be remembered that the course of natural phenomena can be influenced in many ways without the expenditure of energy. An elastic missile rebounding from a rigid plane is a case in point, or a river flowing between its banks.

The production of antiseptics appears to be more and more engaging the attention of the great German colour manufacturers, and yet another compound, rejoicing in the name of potassiumorthodinitrocresolate, has been introduced, which promises to prove of considerable service both to the brewer and to the horticulturist. Messrs. C. O. Harz and W. von Miller have published an account of their investigations with this substance—or *antinonnin*, as it is more generally called—in the *Muenchen Allgemeine Zeitung*, and it appears that a

solution containing but one part in 1500 to 2000 parts of soap-water proves destructive to all common injurious parasites without any deleterious action on the plants. Prof. Aubry, the well-known director of the experimental brewing station in Munich, has examined its disinfectant action on yeast, and finds that the latter, when treated with antinonnin, remained for a long time in a fresh condition in the heated workrooms, whilst untreated yeast rapidly underwent decomposition. A closer examination showed that all the specimens exhibited destruction of bacteria, while the yeast itself proved resistant to even stronger solutions, up to 5 per cent. Numerous other experiments have been made with this substance, and so far it promises well, being also odourless and very inexpensive. Whether this new antiseptic will succeed in carrying out all that is hoped of it, remains to be seen; meanwhile it may be regarded as an interesting, and possibly important, contribution to our list of disinfectants.

MESSRS. MACMILLAN AND CO. will issue in the course of November a further instalment of their "Cambridge Natural History." The volume is mainly devoted to insects, being the first part of a complete treatise on the subject by Mr. David Sharp, F.R.S. Introductory sections on Peripatus and on Myriapods are contributed respectively by Mr. Adam Sedgwick, F.R.S., and by Mr. F. G. Sinclair. The volume is the fifth in the series, and will be followed at no long interval by the second volume, in which various contributors deal with worms and Polyzoa. The ninth volume, in which Mr. A. H. Evans treats of birds, may be expected before the end of next year. Among Messrs. Macmillan's announcements for next week, one of the most important is that of an exhaustive work on "The Structure and Development of the Mosses and Ferns" (Archegoniatæ), by Dr. D. H. Campbell.

WITHIN the past few days, a bulky bundle of new publications of the U.S. Geological Survey has been added to the many reports and memoirs of the Survey already lying on our table. The amount of work represented by these volumes is so exceedingly great, that limits of space prevent us from attempting to describe and discuss the ground covered in them. We propose, however, to give in an early issue a general account of the recent publications of the Survey, and content ourselves at present with the bare statement of the volumes received during this month. First of all, we have to acknowledge the receipt of the fourteenth annual Report of the Survey, in two parts. Part 1 contains the report of Mr. J. W. Powell, the Director, on the operations of the Survey for the year ending June 30, 1893, and part 2 (a volume of six hundred pages) contains papers on geological subjects, among which we notice—the potable waters of Eastern United States; the natural mineral waters of the United States; measurements of river discharges; the laccolitic mountain groups of Colorado, Utah, and Arizona; the gold-silver veins of Ophir, California; geology of the Catoctin Belt; tertiary revolution in the topography of the Pacific Coast; the rocks of the Sierra Nevada; pre-Cambrian igneous rocks of the Unkar Terrane, Grand Cañon of the Colorado. Two monographs of the U.S. Geological Survey have been received, viz. vols. xxiii. and xxiv. The former deals with the "Geology of the Green Mountains in Massachusetts," by Messrs. R. Pumpelly, J. E. Wolff, and T. Nelson Dale; and the latter contains Prof. R. P. Whitfield's text and drawings of the Mollusca and Crustacea of the Miocene formations of New Jersey. Both these valuable monographs are profusely illustrated. Finally, *Bulletin* Nos. 118-122 of the Survey have come to hand. No. 118 is a geographical dictionary of New Jersey. The next *Bulletin* contains the report of a geological reconnaissance in North-west Wyoming, with special reference to economic resources; No. 120 is on the Devonian system of Eastern Pennsylvania and New York. No. 121 is a bibliography of North American palæontology for the years 1888-92, inclusive; and No. 122 contains the results of the primary triangulation executed by the Survey during the past twelve years—that is, since the commencement of work upon the topographic atlas of the United States. In conclusion, we wish only to remark that the gratitude of geologists is due to the United States Government for providing the funds to publish so many works, not only of national but also of international importance.

THE current number of the *Journal de Physique* contains a paper by MM. Abraham and Lemoine on the measurement of very high potentials by means of a modified attracted disc electrometer. Two forms of instrument are described, the one for standard measurements, and the other, which is of simple design, intended for measuring potentials up to 100,000 volts to within about one per cent. In the standard instrument, which resembles a modified Kelvin electrometer as designed by M. Baille, the movable disc is suspended from the beam of a short-beam balance, the extent of the movement being limited by stops. In order, when desired, to make the movement of the balance beam stable, an auxiliary knife-edge is placed below the chief knife-edge of the beam, and weights are placed in a pan suspended from this auxiliary knife-edge. The attracted disc is maintained centrally within the guard-ring by means of three fine fibres. The simplified form of electrometer is, however, the one which exhibits most novelty. In this instrument the attracted disc is carried by a rod attached to one arm of a Roberval's balance. The movements of the balance, which is limited by stops, is noted by means of a long pointer attached to one of the horizontal bars of the moving parts. Finally, the adjustments of the guard-ring and attracted disc are not made by means of a complicated system of adjusting screws, but by the simple bending of their supports. These supports are made of soft copper wire, and, in the case of the guard-ring, have an S shape. This manner of allowing for the adjustment of the parts of a piece of apparatus is one which will very often be found of use, and we may mention that lead wire is particularly well suited for the purpose. The authors have made a series of experiments to test what is the maximum distance between the attracted and attracting discs it is allowable to use, and find that the greatest distance to be equal to half the width of the guard-ring. In making their measurements, the authors have used a novel method of obtaining a high potential which should remain steady for some minutes. Their arrangement consists of an electrostatic electric machine driven at a uniform speed by a small motor. The poles of the machine are joined to two points, between which a continuous stream of sparks passes. One of these points is connected to earth, and the other by means of a poor conductor, such as cotton soaked in paraffin oil, to the inner coating of a Leyden jar. Under these circumstances it is found that the potential of the interior coating of the jar is very constant. Thus in a series of measurements recorded by the authors, the maximum change in six minutes amounted to only 1 part in 1000, the potential being about 20,000 volts.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*, ♀) from East Africa, a Smith's Dwarf Lemur (*Microcebus smithi*) from Madagascar, presented by Mr. E. Dyer; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mrs. Vernon Biden; a Polar Bear (*Ursus maritimus*, ♂) from Spitzbergen, presented by Mr. Arnold Pike; two Masked Parrakeets (*Pyrrhulopsis personata*) from the Fiji Islands, a Blue and Yellow Macaw (*Ara ararauna*) from South America, a Peregrine Falcon (*Falco peregrinus*, var. *Anatum*) from North America, a Night Heron (*Nycticorax*

griseus), European, an Antarctic Skua (*Stercorarius antarcticus*) from the Antarctic Seas, presented by the Hon. Walter Rothschild; two Senegal Touracous (*Corythaix persa*) from West Africa, presented by Mr. I. J. Roberts; three Blackcaps (*Sylvia atricappilla*), a Nightingale (*Daulias luscinia*), British, presented by Mr. Poynter; a Wall Lizard (*Lacerta muralis*) from Sicily, presented by Mr. A. M. Amster; a Dwarf Chameleon (*Chamæleon pumilus*) from South Africa, presented by Mrs. S. Jackson; two Squirrel Monkeys (*Chrysothrix sciurea*) from Guiana, a Spotted Eagle (*Aquila nævia*) from India, three Weka Rails (*Ocydromus australis*), four Tuatera Lizards (*Sphenodon punctatus*) from New Zealand, deposited; two Grisons (*Galictis vettata*), a Coypu (*Myopotamus coypus*) from South America, two Western Boas (*Boa occidentalis*) from Paraguay, purchased.

OUR ASTRONOMICAL COLUMN.

SUN-SPOT OBSERVATIONS IN 1894.—In a *Separatabdruck aus der Vierteljahrsschrift der Naturforschenden Gesellschaft in Zürich*, Jahrgang 4, 1895, Dr. A. Wolfer brings together some results relating to the sun-spot statistics made in Zürich and elsewhere for the year 1894. The pamphlet opens with a determination of the constants for reducing the observations of each observer to one scale.

The mean observed relative number of spots for 1894 came out as 78·0 as against 84·9 in 1893, showing a distinct decrease. The secondary variations were also very prominent during this year; further, between two very low minima there occurred a prominent maximum lasting from May to July. Nevertheless there was on the whole a general decrease, making it possible to determine the epoch of the last important maximum. Having plotted the relative number of observed sun-spots for the three years 1892–94, and connected them together, the smoothed curve indicated a maximum at 1894·0. The length of the elapsed period, that is, from maximum to maximum, became

$$1894{\cdot}0 - 1883{\cdot}9 = 10{\cdot}0,$$

and the interval between the last minimum and the present maximum

$$1894{\cdot}0 - 1889{\cdot}6 = 4{\cdot}4.$$

Dr. Wolfer makes a comparison of the sun-spot numbers with the variations of the magnetic declination. Here there seems to be a very good agreement, and the curves for both are very similar. The epoch of the maximum magnetic variation, independently determined, occurs in August 1893 or 1893·6, which coincides exactly with the secondary rise of the curve of relative spot numbers. This secondary rise in the curve occurs just before the time of maximum deduced from the smoothed curve, and suggests rather that the former date should represent the chief sun-spot maximum. Dr. Wolfer, however, is not of this opinion, and prefers to hold to the date gathered from the mean curve. The pamphlet concludes with a tabular statement of each of the observers' individual observations for the year 1894, together with reference to the literature.

PLANETARY PERTURBATIONS.—In No. 3312 of the *Astronomische Nachrichten*, Prof. A. Weiler gives another paper on the subject of long-period and secular perturbations. The particular case considered is that of the disturbance of a planet, having a mean motion approximately twice that of the disturbing planet, and is really a special case of the more general problem of perturbations already treated in earlier numbers of the same journal. We cannot indicate here the mathematical formulæ which are given, and much of which would be unintelligible without the earlier papers, but attention may be called to one of his results.

When the commensurability in the periods of the disturbed and disturbing planets becomes very close, that is if $\delta = 1 - 2\mu$ be very small, where μ is the ratio of the two mean motions, the series by which the perturbations are expressed is not convergent, and the problem is apparently insoluble. Such a result is inconsistent with the regularly observed motions of the planets, and therefore points to some error in the assumptions on which the solution of the problem is founded. This error Prof. Weiler traces to the treatment as constant of the semi-axis major of the disturbed planet's orbit. The justice of this remark is illustrated by a reference to the arrangement of the asteroids in space, whose distribution offers peculiarities explicable on the hypothesis that the mean daily motion is variable if the approximation to commensurability oversteps a definite limit. Taking a list of twenty-five asteroids, wherein the value of $\delta = 1 - 2\mu$ is less than one-fifteenth, he shows that none have a period giving a mean daily motion very approximately twice that of Jupiter (598″·3). The mean daily motion of these twenty-five lies between 562″·2 and 640″·2, but none come between 572″·6 and 614″·4; that is, the mean motions separate on both sides of twice that of Jupiter. The force of this illustration is somewhat impaired if the list be made to comprise those more recently discovered. The asteroids Nos. 332 and 381 have mean motions of 605″·5 and 613″·5, respectively, and it should further be remembered that in the whole list of asteroids, there are only five whose means approach the lower limit of 562″. This remark simply refers to the value of the illustration, not to the accuracy of the fact it is called in to support.

THE SYSTEM OF α CENTAURI.—The meridian measures of the positions of α_1 and α_2 Centauri, made at the Cape in 1879–1881 have been utilised by Mr. A. W. Roberts for a determination of the relative masses of the two stars, and other data connected with the system (*Ast. Nach.* No. 3313). The place of the centre of gravity for 1880 is given as R.A. 14h. 31m. 27·537s., declination − 60° 20′ 20″·63 ± 0″·13; proper motion in declination (1880) = + 0″·750 ± 0″·005; proper motion in R.A. (1880) = − 7″·291 ± 0″·032. For the relative masses of the two stars, the values derived are 51 to 49 ± 1/50 of the amount.

According to the results obtained by Mr. Roberts, α_2 Centauri is very slightly heavier than the sun, while α_1 is about two-hundredths lighter. Since α_2 is now between five and six times brighter than α_1, it must have by far the brighter surface. Taking a mean of the different values which have been obtained for the sun's brightness in relation to the stars, "it would appear that α_2 Centauri is as bright as our sun, while α_1 is about five times fainter. α_1 Centauri is accordingly some distance on the downward track from the dignity of a sun to that of an ordinary planet; while α_2 Centauri is, as regards light, size, and mass, a twin-brother of our sun." Spectroscopic observations will furnish another method for determining the relative masses, but, in order to improve on our present knowledge, the observations of velocities must be accurate to within one or two tenths of a mile per second.

HOLMES' COMET.—This comet, which has presented such peculiarities both in its physical structure and the form of its orbit as to make it one of the most remarkable comets of short period, has been made the subject of an elaborate investigation by Dr. H. J. Zwiers. Taking into account the action of Jupiter and Saturn, but neglecting that of the Earth, to which, owing to the great perihelion distance of the comet, it cannot make any close approach, Dr. Zwiers is led to fix the date of the next perihelion passage on April 27, 1899, and gives an ephemeris commencing on February 16, 1898, the earliest date at which a search is likely to be successful. The theoretical brilliancy is then 0·0063, and when last seen in 1893, the brilliancy was expressed by 0·0118. In April and May, when the comet will be well situated for observation in the southern hemisphere, this latter quantity will be exceeded, and will approach that, that the comet possessed in January 1893, when it underwent such a remarkable change in its appearance. If the comet retains its stellar-like character, the difficulty in detection will no doubt be increased, but an early discovery is eminently desirable.

ON THE HABITS OF THE KEA, THE SHEEP-EATING PARROT OF NEW ZEALAND.

THE kea, the mountain parrot of New Zealand (*Nestor notabilis*), has earned considerable notoriety from its remarkable habit of attacking living sheep. It is commonly stated that the natural food of this bird consists of insects, fruit, and berries; and that it has developed a taste for a carnivorous diet only during the last thirty years. Mr. Taylor White, however, has recently pointed out (*Zoologist*, August 1895) that the various statements on the habits of this bird have all been derived from second-hand information; and, as the habitat of the parrot is on the tops of Alpine ranges, owners of sheep and shepherds who

[illegible] in summer search the mountain tops for their stock, are the men best fitted to tell us about the habits of the bird. On observations made during such experiences Mr. White bases his own account. In the district with which this writer was acquainted, the kea always lived high up on the mountains, among rocks and boulders, a long distance above the forest-line: in such a situation, of course, berries and fruits were out of the question, and the bird appeared to live on lichen and any insects it could find. Even when the ground was covered with several feet of snow, and when roots and other food were out of reach, lichen growing on steep rocks would still be obtainable by the bird. The view that the diet of the kea generally consists of fruit and berries would thus appear to be erroneous.

It will be remembered that Wallace and others state that the kea regards the kidneys of sheep as a "special delicacy," and that it attempts to burrow into its victim in such a way as to reach this part. Mr. White, however, opposes this prevalent view, and regards it as probable that the bird desires to obtain the blood of the sheep rather than the kidneys; and in support of this view states that he has never seen a dead sheep attacked by keas. The fact that the kea so frequently pierces the body of a sheep in the region of the kidneys is due to the position it takes on the back of its victim to maintain a firm hold—a position from which it cannot be easily dislodged, as it could from the head or rump of the sheep. In corroboration of this Mr. White mentions that sheep with long wool are more frequently attacked than animals with short wool; as apparently the long wool gives the bird better facilities for holding on with his feet when drilling a hole into the back of the sheep. It is not very easy to conjecture how this habit of attacking sheep was first acquired by the kea. In winter time the sheep are covered with snow, and often have icicles hanging to their wool; and it is suggested by Mr. White that keas may have mistaken sheep so disguised for snow-covered patches of rock. It may further have happened that when searching the supposed rocks for insects the birds in some cases would taste the blood of the sheep. "When some of the birds had once found out that the blood of the sheep was good for food, others were soon initiated into the performance." It is possible that in some such manner the kea may have gradually acquired this curious and unattractive habit which renders the bird such a pest to the New Zealand farmer.

W. Garstang.

THE PENETRATION OF ROOTS INTO LIVING TISSUES.

THE capacity possessed by the roots of certain parasites, such as *Cuscuta*, to penetrate into the tissues of their host, is apparently an unique, not to say a remarkable phenomenon. A little reflection, however, upon the powers of roots in general, leads us to doubt whether this property is really as restricted as the first glance would lead us to imagine; and when we peruse Prof. Pfeffer's work upon the pressure of the root, and find that, for instance, the root of the common bean exerts during its growth a pressure of some 400 gms., we realise that this mechanical action alone might suffice to drive the growing root of most plants into living tissue, if circumstances necessitated such an expediency. This is evidently an important point, and touches upon the evolution of the higher parasites; it is only remarkable that it has so long remained untouched. We must now thank George Peirce for taking up this neglected [illegible], and placing it upon a sure basis (see *Bot. Zeit.* September 1894). The question first to be decided was whether the pressure which Pfeffer had found in the growing roots was in itself sufficient to force the roots through living tissue. For the determination of this, iron models of roots weighted up to 27[illegible] gms. were employed. The apices of these were placed upon a cube cut from a potato, and the whole surrounded with damp sawdust to keep the living substance fresh. After an interval of twenty three hours, it was found that the iron point had penetrated 1½ mm. into the potato. Again, a similar model weighted to 320 gms. was driven in twenty-four hours through the cork layer and 2 mm. of parenchyma of an uncut potato. Also a root model placed on the stem of *Impatiens sultani*, one and a half centimetres thick, pierced this in less than twenty hours when 300 gms. weight were employed.

Thus a pressure inferior to that found by Pfeffer in the root of *Vicia faba* was sufficient to drive an iron model an appreciable distance through the living tissues of the potato.

It was far from certain, however, whether a pressure which was ample to impel a rigid iron rodlet against a considerable resistance would have equal efficiency in the case of a root, the pressure in which arose from so uncertain and inextricable a source as its life.

There were many facts both *pro* and *contra*.

The acid substance or substances, which it would seem that most roots excrete during their growth, might possibly facilitate the root's power of penetration. Just as many fungi eat their way, as it were, into the solid wood of their host by means of ferment-like substances which they secrete and pour out upon their substratum, so might the roots perhaps be expected to soften and prepare their way by means of their acid excretions. Against the supposition could be raised the fact, already broached, that the forces, impelling the root-apex forward, are derived from the vital activities of that structure, and than these nothing can be more sensible to change of surroundings, or less to be reckoned upon by us, whose conceptions of anything dealing with life are yet shrouded over with the darkest obscurity.

But to pass from speculation to facts, we find that Peirce tested this point by experiments on the seedlings of *Brassica napus* and *Sinapis alba*. He took a potato, and split it in half; on one of the halves he cut a number of small slits, into each of which he inserted a seed of the plant under observation. He then placed the potato-halves together, binding them tightly with string. The whole contrivance was placed in a vessel containing damp sawdust, care being taken that the cut surfaces of the tuber lay horizontally. After an interval of twelve days the specimens were examined, and although some were found to have grown between the cut surfaces (for nearly all had germinated), yet others had pushed their rootlets vertically downwards so as to penetrate the substance of the potato. In some instances so vigorous had been the growth that the rootlet had traversed the whole thickness of parenchyma, pierced the hard corky layer of the surface, and then reached the sawdust without.

Anatomical examination of the root and surrounding potato tissue showed several peculiarities. In the first place, the young root was almost devoid of the customary clothing of hairs: secondly, the cells of the potato had undergone alteration, inasmuch as those which were in immediate contact with the advancing root were much contorted and torn, whilst two or three layers neighbouring on the injured elements had undergone division by walls parallel to the long axis of the root, and had subsequently become corky in nature. By this means the intrusive rootlet was enclosed within a corky cylinder or sheath, cutting it off more or less perfectly from the living, unharmed tissue of the tuber. The starch grains were in every case unaltered, but Prunet, in his research on *Cynodon*, and Peirce, in his examination of one of his specimens of *Pisum*, noticed certain grains in the neighbourhood of the root apex which were partially disintegrated. This, however, is not a necessary consequence of ferment action; indeed, a check experiment of Peirce's leaves little doubt that the disintegration results in these cases from the activities of bacteria which had gained an entrance with the root. Glass tubes closed and pointed at one end were sunk, like the iron models already mentioned, into potato tissue. In one instance the apex of the glass was surrounded by "corroded" starch-grains. Here there could be no question of ferment formation, and evidently bacteria were adherent to the apex.

"So far the experiments had proved that the thin, delicate, and pointed roots of rape and white mustard are able to penetrate living tissues. Peirce carried the matter further by testing the powers of the blunt rootlets of *Pisum* and *Vicia faba* to do likewise. The rootlets of germinating seeds of these were placed in glass tubes into which they accurately fitted, and their apices placed in contact with the surface of a cube of potato. The seed and glass tube were rigidly held by layers of gypsum, in which a gap was left for the extension of the plumule. The whole was kept moist by damp sawdust. After three days the roots were found to have pierced the living tissue to the extent of 7.5 mm.

Other experiments were made on the same plants in which other tissues, such as stem of *Impatiens sultani*, leaves of Echevaria and Aloe, petioles of Rheum, &c., were substituted for the potato. These also were penetrated by the rootlets.

In some instances, however, such as leaves of Aloe and petioles of *Rheum officinale*, the pabulum was evidently unsuited to the healthy existence of the root, for after a short

period of growth the apex of this organ became more or less spherical, and finally withered away.

Similar results had been obtained with the haustoria (modified roots) of Cuscuta, in a former research of George Peirce's.

Another interesting achievement of the same worker was to grow specimens of Pisum as parasites upon other plants, from the seedling stage until flowering. The host which gave the most favourable results appears to have been *Impatien[s] [S]ultani*.

The young Pisum grown under these unwonted conditions produced an almost normal root system, with numerous side branches; but the stem was stunted in its growth, although it bore leaves and a few flowers. The roots, it may be mentioned, were here also devoid of hairs. This experiment is extremely interesting in a great many ways. It shows, in the first place, how fine is the line of demarcation between an ordinary earth-grown plant, such as Pisum, and a phanerogamous parasite, especially a partial parasite like mistletoe.

Again, it has a physiological interest: it is suggestive of a new path of research. A strict and careful comparison of the details of outward form and internal anatomy in a normally grown Pisum, or other plant, with those found in one which is, so to speak, an induced parasite, must, beyond all doubt, shed much light upon the relationship between the shape and structure of an organism and its surroundings.

We know but too little of this branch of biology at present. Why an organ should be shaped this way in one individual and that way in another, may indeed be partially answered in some cases; but these instances are few, and the answers are incomplete, to say the least of them.

RUDOLF BEER.

DR. A. SCHMIDT'S THEORY OF EARTHQUAKE-MOTION.

[NOTE. The following pages contain a summary of an interesting but little known paper by Dr. August Schmidt, of Stuttgart. An English translation was prepared by the late Dr. E. von Rebeur-Paschwitz for the *Seismological Journal of Japan*, but arrived too late for publication in the concluding volume of the series. The original being too long for insertion in NATURE, I have condensed it at the translator's request, at the same time adhering as closely as possible to the author's words. The title of the paper is "Wellenbewegung und Erdbeben ein Beitrag zur Dynamik der Erdbeben" (*Jahreshefte de[s] Vereins fur vaterl. Naturkunde in Wurttemburg*, 1888, pp. 248-270). In a later paper (same journal, 1890, pp. 200-232), Dr. Schmidt applies his theory to the Swiss earthquake of January 7, 1889, and the Charleston earthquake of August 31, 1886. C. DAVISON.]

SEISMOLOGISTS assume the propagation of earthquake-waves to take place uniformly in all directions; they regard the coseismal or wave-surfaces as concentric spheres, the rays as straight lines normal to the spheres. This, however, is an entirely unjustified assumption, which certainly facilitates the calculations, but leads to very doubtful results in determinations of the velocity of propagation and of the depth of the earthquake-centre. It is impossible that seismic rays should be straight lines, because the conditions on which the velocity depends undergo change with increasing depth below the surface. Though experimental determinations of the velocity do not agree with the theoretical value $\sqrt{e/d}$, yet it is clear that the velocity must depend on the density and elasticity of the rocks through which the wave is propagated. Now, the modulus of elasticity, owing to increased pressure, must increase with the depth below the surface; and therefore the velocity of the earthquake-wave must also increase with the depth.

As the velocity of propagation increases, the energy of a vibrating particle diminishes; and thus, as is well known to be the case, earthquakes should be less noticeable in mines than on the surface of the earth.

Amendment of Hopkins' Law.—Let us imagine a wave emanating from a deep centre and propagated in all directions. A vertical plane through the centre cuts all the successive coseismal surfaces, as well as the earth's surface. Let us suppose the section of the latter to be a horizontal straight line. The lower parts of Figs. 1 and 2 show the successive positions of the coseismal surfaces from minute to minute. Fig. 1, with its equidistant concentric coseismals and its straight rays, corresponds to the ordinary earthquake theory. Fig. 2, with its excentric coseismals approaching each other as they rise and with its curved rays convex downwards, represents our new theory. The horizontal straight line, dividing the upper part of the figures from the lower, represents the surface of the earth. In both figures, the rays at first appear equally distributed in all directions from the centre; in Fig. 1 they remain so, but in Fig. 2, in order to continue normal to the wave-surfaces, they must diverge at a much more rapid rate below than above, thus becoming convex downwards. Of course, Fig. 2 only represents a special law of increase of velocity with the depth—the velocity is supposed to vary as the depth—but the general character of the figure with its rays convex below remains the same if the law is a different one.

A comparison of the figures shows that in Fig. 2 there is a greater condensation of the seismic rays, and therefore a greater intensity of the shock, in the neighbourhood of the epicentre, and this corresponds better with the effects observed within the area of greatest disturbance.

But more important for our purpose are the sections of the earth's surface contained between two successive coseismals. Each of these sections is a measure of the distance through which the wave appears to progress from minute to minute at the surface. In reality it progresses obliquely from below in the direction of the rays, and the real distance through which it moves is smaller than the apparent one. We can only observe the apparent velocity at the surface. If we have at our disposal a sufficient number of good time-observations, we can draw the horizontal coseismal lines on a map and determine the apparent velocity from their relative distances. In both figures, the apparent velocity has its greatest value at the epicentre and decreases outwards. In Fig. 1, it gradually approaches asymptotically the true value in the direction of the rays. This is the law which Hopkins propounded in 1847. In Fig. 2, the apparent velocity at first diminishes rather rapidly, until it reaches the value of the true velocity at the depth of the centre, but afterwards it again increases gradually with the distance. We thus arrive at the following amendment of Hopkins' law, which will be expanded afterwards: the apparent velocity at the surface is never less than the true velocity at the centre, and varies with it.

Differences in Earthquake Velocities.—According to the old theory, every substance ought to possess its own velocity, dependent on its internal structure. The limit, which is defined by Hopkins' law as the lowest possible value of the apparent velocity, ought always to be the same in any given region. Experiments by Pfaff, Mallet, and Abbot lead to different values for different substances, as was to be expected. But they also show considerable variations in the same material, the velocity increasing with the strength of the initial impulse. Real earthquakes show even larger differences in velocity than artificial ones, and often earthquakes of less intensity are propagated with a greater velocity in the same region than very strong ones.

These differences are inconsistent with Hopkins' law. To be explained by the old theory, they require for the centres of earthquakes with great velocities an enormous depth below the surface, a near approach to the centre of the earth, for an earthquake emanating from the centre itself would arrive simultaneously at all points of the surface. With our new hypothesis, such differences are necessary, and even with the largest velocities the earthquake-centre may be at a considerable distance from the centre of the earth.

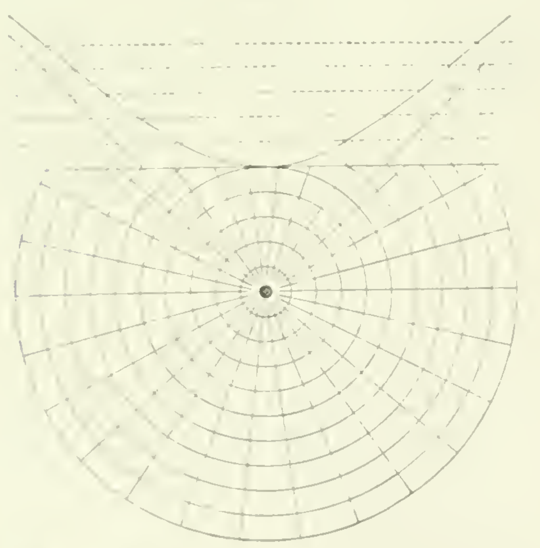
Proof of the Law.—The law that the velocity at the surface is never less than that at the earthquake-centre includes Hopkins' law. This indicates that the law is a general one. Its mathematical demonstration is contained in the law of refraction. We may distinguish the following three velocities: (1) the velocity at the centre, u_1; (2) the true velocity at the surface, *i.e.* that part of an earthquake-ray through which the wave progresses in one minute, u; (3) the apparent velocity at the surface, *i.e.* the horizontal distance between two successive coseismals corresponding to an interval of one minute, v. As an example, let us take in Fig. 2 the horizontal distance between the fourth and fifth coseismals from the epicentre as a representative of v, and let the section of the ray between the same coseismals near the surface represent u, and the distance between the centre and the first coseismal u_1. Then, if α be the angle between the ray and the vertical at the point where it meets the surface, we have $v = u \sin \alpha$; and, if α_1 be the angle which the same ray makes with the vertical through the earthquake-centre, we have by the law of refraction $v = u/\sin \alpha = u_1/\sin \alpha_1$.

Now, let us consider the different rays emanating from the

earthquake centre. When a_1 is equal to zero, v is infinitely great. As a increases, v decreases, until $a_1 = 90°$. This corresponds to the ray which starts horizontally from the centre, and at the point where this ray reaches the surface we have $v = u_1$. When a_1 becomes obtuse, the value of sin a_1 decreases again, and v increases, though more slowly because the rays diverge more and more: but at an infinite distance v would again be infinitely great.

The only condition by which our law is bound is that the true velocity of the wave is always the same at the same depth; but the variation of velocity may follow any law. The law would even remain true if the velocity were to decrease with the depth; but in this case the rays would be concave downwards, and only a few would reach the surface. But, as we have every reason to believe that u increases with the depth, it follows that the rays must be convex downwards; and not only the ray which is horizontal at first bends upwards, but all rays do so in time. The whole disturbed area of an earthquake is thus divided into two zones: an inner circle in which the apparent velocity v decreases as the distance from the epicentre increases, and an outer ring in which v increases with the distance up to infinity. The inner circle is the region of the direct rays, the outer ring that of the earthquake energy which by refraction is brought up from below. The smallest value of v, corresponding to the boundary between the two zones, measures the velocity of propagation at the depth of the centre.

Fig. 1



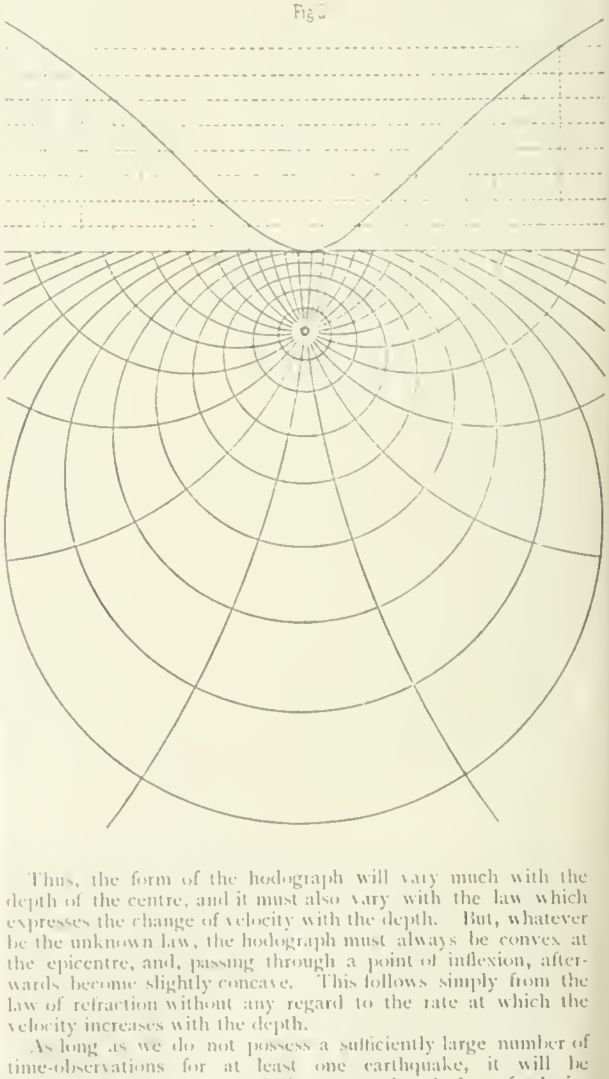
* The [illegible] curvature of the earth's surface, which we have [illegible], will consist in a diminution of the rate at which the velocity increases in the outer zone.

The Earthquake Hodograph.[1] The law connecting the variations in the apparent velocity at the surface is best expressed by the upper parts of Figs. 1 and 2. At the points where the surface line is cut by the coseismals, normals are erected to the surface of 1, 2, 3, &c., units in length, representing the difference in time from that at the epicentre. A curve passing through the ends of these normals represents what we call the hodograph. The greater the inclination of the curve to the vertical line, the less is the apparent velocity, v, at the corresponding point of the curve. Where the curve is horizontal the velocity is infinitely great, where it is convex downwards the velocity decreases outwards, where it is concave the velocity [illegible]. The hodograph in Fig. 1 is the hyperbola of von [illegible] Minnigerode. If we use the same scale for the units of time and velocity, the hyperbola is rectangular and the asymptotes are directed towards the centre. In Fig. 2, the hodograph is no longer hyperbolic; at the epicentre it is horizontal and convex downwards, gradually approaching a [illegible] inclination at a point of inflexion, after which it becomes concave downwards, and gradually becomes horizontal again at infinity. If, in the lower part of the figure, we follow the ray which leaves the centre horizontally until it reaches the surface, a normal erected at this point passes through the point of inflexion.

[1] [illegible] Hamilton to a curve which re[illegible] the [illegible] velocity of a moving point. We do not [illegible] of [illegible] the same for our purpose.

It is important to study the changes in the form of the hodograph as the depth of the centre gradually diminishes. The result is that the two points of inflexion move towards the epicentre, the convex portion becomes smaller, and so also does the "inner zone" of the disturbed area. When the centre and epicentre coincide, the convex portion of the curve and the inner zone of the disturbed area disappear entirely: the hodograph consists of two symmetrical concave branches which meet at an angle at the centre. This suggests to us how we should explain the results of measurements of velocities in artificial earthquakes. In a shock produced at the surface of the earth, the velocity must increase from the centre outwards. The stronger the charges of gunpowder are, the longer are the distances that can be employed in the experiments, and the greater the mean values of the velocity obtained.

Fig. 2



Thus, the form of the hodograph will vary much with the depth of the centre, and it must also vary with the law which expresses the change of velocity with the depth. But, whatever be the unknown law, the hodograph must always be convex at the epicentre, and, passing through a point of inflexion, afterwards become slightly concave. This follows simply from the law of refraction without any regard to the rate at which the velocity increases with the depth.

As long as we do not possess a sufficiently large number of time-observations for at least one earthquake, it will be impossible to draw any conclusion concerning the law of velocity from the form of the hodograph. Even with the best observations, we can never, in drawing the hodograph, expect that all points will fall on a regular and continuous curve. But what we may expect is that, with a sufficiently large number of observations, the points will be distributed equally on both sides of such a curve. The hodograph contains the observations from places

in all possible directions from the epicentre combined in a single plane. If the velocity is different in different directions, in the general figure these differences will be eliminated when the number of observations is large enough, and the result will be a curve free from local disturbances.

Although the time has not yet come for us to determine the definite form of an earthquake-hodograph, yet we know enough from the best examined earthquakes to decide whether the hodograph is an hyperbola or a curve with points of inflexion, whether Hopkins' law is confirmed by the observations, or an increase of velocity is noticeable in the outer zone of the disturbed area.

The best example for such an investigation is contained in von Seebach and Minnigerode's discussion of the earthquake of March 6, 1872, in Central Germany. An inspection of the map of coseismals published by them is sufficient to show that the horizontal coseismals are crowded together in a striking manner near Gottingen and Leipzig, at a distance of sixteen (German) miles from the epicentre. Accordingly, in drawing the hodograph we see how badly the hyperbola suits the observations. Several points which are most valuable for the determination of the epicentre, because they are nearest to it, and which agree most perfectly with one another, must be rejected in constructing the hyperbolic hodograph, in order that the earthquake may not begin at the surface of the earth until 1½ minutes after it was actually observed at five different places at five to six miles distance from the epicentre. For sixteen miles the hyperbola leaves all the best observations below it, after which nearly all points remain above it until it ends at Breslau, at a distance of fifty-seven miles from the epicentre. At this place a magnetic needle was found swinging by Prof. Galle at 4h. 5m. 25s., Berlin time, but the shock itself may have occurred several minutes earlier. The hyperbola is made to pass exactly through the point corresponding to this time, for otherwise its vertex would have to be placed still higher than it is now, and this would increase the already existing disagreement between the calculated time of the beginning of the earthquake and the actual observations.

How well, on the contrary, are the observations represented by a curve the vertex of which is a little below 3h. 55m., and, being convex downwards, passes at a distance of seven to eight miles between 3h. 55m. and 3h. 56m., reaches its points of inflexion at about eleven miles distance with a slope corresponding to 2·5 miles per minute, and then leaving some points on one side and some on the other, passes through Tübingen (36·7 miles), the last trustworthy point, until it reaches Breslau one minute before the observed time, with a velocity of at least fifteen miles a minute.

The Herzogenrath earthquake of October 22, 1873, leads to somewhat similar results. In drawing the hyperbolic hodograph, some of the best observations, those used for determining the position of the epicentre, have to be rejected altogether, while others must be supposed to err by as much as two or three minutes. But a curved line, passing through the mean positions of the points, is concave throughout on its lower side, with a large curvature at the epicentre. The figure certainly differs little from the form of the hodograph corresponding to a centre at the surface, and the inner zone is a circle of not more than four kilometres radius.

Thus the best investigated earthquakes at our disposal show that the observations agree much less closely with the older theory of concentric earthquake-waves, straight rays and hyperbolic hodograph, than they do with the new theory of a velocity of propagation increasing with the depth, rays convex downwards, and a hodograph with points of inflexion.

The Determination of the Depth of the Centre.—If the law connecting the velocity with the depth were known, we should be able to calculate the forms of the corresponding rays and hodograph, and to find a relation between the depth of the centre and the form of the hodograph. In Fig. 2 we have started with the simplest assumption, and supposed the velocity to vary as the depth. As this law is an entirely arbitrary one, the figure can only give a nearer approach to the truth than the theory represented in Fig. 1. If, for instance, the modulus of elasticity were to vary as the depth, the velocity would change much more rapidly near the earth's surface than far below it; and the fact that the perceptibility of earthquakes decreases so rapidly as the depth increases, certainly indicates that a rapid change in the velocity takes place immediately below the surface. Consequently, in calculating the depth of the centre according to our law, we should find too large a value. Other difficulties in determining the depth of the centre are our ignorance of the true superficial velocity, and the uncertainty as to the form of the hodograph, especially the doubtful position of its points of inflexion. But, in spite of all these difficulties, we may consider it as a rule that the depth will increase with the radius of the inner zone of the disturbed area, and that it will certainly always be smaller than this radius.

On the other hand, a minimum value of the depth may be found by means of the tangent at the point of inflexion. This tangent in Fig. 2, like the asymptote in Fig. 1, makes an angle of 45° with the horizon, because in both figures the central velocity (u_1) was taken as the time scale. While in Fig. 1 the asymptote passes through the centre, in Fig. 2 the tangent at the point of inflexion passes above it. Now, let us imagine the depth of the centre in Fig. 2 to remain the same, as well as the velocities u_1 at the centre, and u at the surface; but let the increase of velocity be no longer uniform as before, but be principally restricted to the neighbourhood of the surface. The consequence will be that the rays will differ little from straight lines at first when they leave the centre, and that the principal increase of curvature will be near the surface. The point of emergence of that ray which leaves the centre horizontally, will move to a greater and greater distance, and, as the same is the case with the point of inflexion of the hodograph, its tangent at that point will be displaced parallel to itself downwards; and when the whole change is imagined to take place in the surface itself, the hodograph will coincide with Seebach's hyperbola, and the tangent at the point of inflexion becomes an asymptote and passes through the centre.

Thus, with a hodograph adapted as well as possible to the existing observations, we find a depth of more than five, and less than ten, geographical miles for the earthquake in Central Germany, and a depth of less than three kilometres for the earthquake of Herzogenrath. Each of these earthquakes represents a special type. Type I., with a very small depth of centre and an approximate disappearance of the inner zone, is represented by the earthquake of Herzogenrath: Type II., in which both zones are pretty equally distinct, and the depth is rather considerable, by the earthquake of Central Germany. There may exist a Type III. with a very deep centre, or with small intensity and moderate depth, for which the point of inflexion of the hodograph falls outside the region when the earthquake is perceptible, and where, consequently, the hodograph is convex throughout. Amongst the earthquakes so far studied, for which the mean velocity has been calculated, those with small velocities, which generally have a merely local character, may safely be regarded as belonging to the first type.

THE TOTAL SOLAR ECLIPSE OF AUGUST 8, 1896.[1]

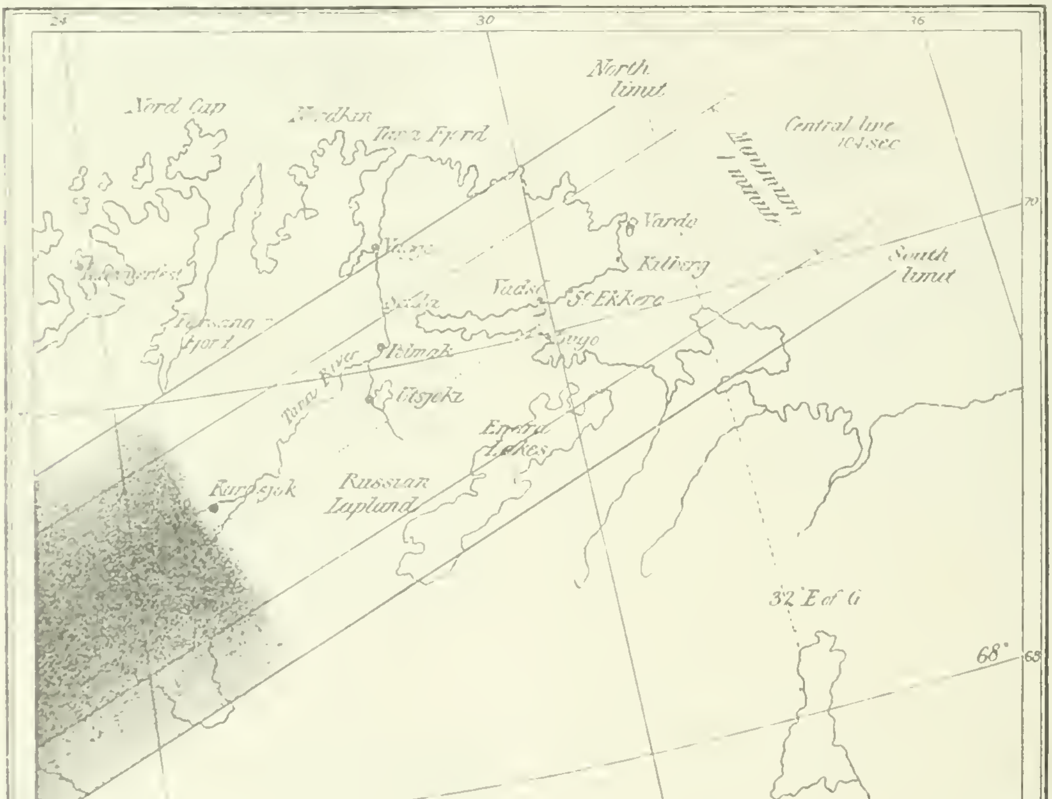
IT having come to my knowledge that some doubts had arisen as to the suitability of Norway as a post of observation for the total eclipse of the sun in 1896, and having had both experience in total eclipse expeditions and of travelling in Norway, I determined to make a special tour of observation both to the west coast, and also to Finmarken, Lapland, and the Russian frontier on the east coast.

In selecting stations in such an exceptional country as Norway, many points must be considered that do not apply to most places; thus it is not enough to know that A is twenty miles from B without also knowing how many fjords lie between, how many peaks three or four thousand feet in height, how many glaciers, and how far they are crevassed, if the mountains are passable, and if so what weight besides himself a man can carry up. Those people who have visited Norway, and the more so those who have travelled in the interior and north of the country, are surprised at the almost impossibility of moving at all except by the fjords and certain made roads. These generally may be said to extend as far north as Trondhjem, latitude 63° 26′; longitude 10° 30′ about. After that, on the north and north-east coast and Russian frontier, roads are the feeblest tracks generally, and the fjord communication only of a special character; the population, except at such places as Tromso, Hammerfest, Vardo, and Vadso, is very scanty, and chiefly confined to the sea coast, and in the latter case subject to consider-

[1] Abridged from a paper read before the Royal Astronomical Society, by Col. A. Burton-Brown (*Monthly Notices*, R.A.S., vol. lv. No. 3).

[illegible] ruing of the season of the year and the nature [illegible] fishing. How far these points would affect an astronomical [illegible] will be seen later on.

From Trondhjem we take a north north east course, passing [illegible]batten, an island of about 800 feet in height, and shortly [illegible] pass the island of Donnæss, at the bottom of the map on the west side, which will be on the border of the shadow during [illegible]; steaming north to Tommen Oe, which will have about [illegible] minute totality, a careful search for stations is kept. Luroe [illegible] low, Oxtinden promontory too much inland. Hest-[illegible], well within the 85° line, and the island of Tranen, near the 12th parallel, are too far west, though the central line passes [illegible]ly; but having a longitude of only 12° 5', the sun is [illegible] low. The height of ground is 3710 feet. Rod Loven [illegible], somewhat further eastward, and Bolgen, a peaked island, close to the central line, are rather too far westward; passing [illegible] Oe and Meloe, crossing the central line, we next miles direct north of the central line, where there is a hill to the north-east of the town. Excellent accommodation can be had there, and a telegraph station exists. Further north is the island of Lande Gode, within the 85° limit. The islands of Lundo and Engelo are on the northerly limit of the shadow of totality, and therefore useless. If Bodo were occupied as headquarters, with a steam launch at the disposal of the party, and Sandhornet, Arnoe, Fleina, Kunnen, or the lighthouse rock of Slot, Bolgen, Rod Loven, or Hestmando as detached stations, a valuable area would be covered, although these positions have the astronomical disadvantage of the sun's altitude being as low as $6\frac{3}{4}°$ to $7\frac{3}{4}°$, and the duration of totality but little over $1\frac{1}{4}$ to $1\frac{1}{2}$ minutes. Yet, owing to the stillness of the atmosphere on the west coast of Norway at that time, and the general freedom from clouds on the horizon, some good results should be obtained. The further fact of the corona being seen through a considerable thickness of watery vapour would have both a spectroscopic and photographic



[illegible] promontory of Kunnen, two or three miles above [illegible] line, a rather inaccessible position of some 2000 [illegible]. The lighthouse island of Slot is, however, in [illegible] desirable position, and Kunnen has a telegraph [illegible] adjacent. Proceeding east-north-east [illegible] island of Fugloe is passed, 2300 feet high, steep and rugged; and [illegible] miles further north, Fleina, about [illegible] feet [illegible] position. On the right is the island of [illegible], with the Sandhornet Mountain of 3300 feet—a rare [illegible], only about five or six miles above the [illegible] minute and a half totality, and the sun an [illegible] 7½°, the longitude being six or seven minutes [illegible]. This position gives an uninterrupted view all round. [illegible] the Arnoe Islands on the west, where there are [illegible] an almost equally good position. [illegible] communication with Bodo, the latitude [illegible] 67° 17' and longitude 14° 24' about, and which is ten interest in comparison with similar observations taken at about double the altitude on the east coast. Although several islands could be used as sites for stations, experience has shown some to be better adapted for many reasons than others. Thus Fugloe is steep and rugged, and has no advantages over Fleina except height; also Omnæs Oe is a troublesome place; Kunnen is an almost inaccessible promontory of chert and granite rocks; the island of Slot has a good anchorage for boats, and the sun would not be masked by Kunnen during totality. Here also is a telegraph station.

Leaving the west coast positions, we reach Tromso, and steaming up to Hammerfest, signs of civilisation die fitfully away. After rounding the North Cape, 71° 10' 40" N., and about 26° E., and steering east, the Nordkin is passed, and from there in a south-east direction we travel along a bleak, inhospitable shore of quartzite rocks to Vardo, on an island; this is about the north-east corner of Norway, a good-sized whaling station, and a fort,

with some second-class hotel accommodation. This place was used as an observing station in 1769 by the Austrian Hell for the transit of Venus; and, being less than twelve miles directly north of the central line of shadow, might be advantageously occupied. It forms the most easterly station; being in longitude 31° 8′, and latitude about 70 22′, it would have a duration of totality of over 1m. 31s., and the sun's altitude will be about $14\frac{1}{2}$°. It is easily accessible, no high ground obstructs the view, and provisions and labour are to be had. Passing south down a dreary coast of quartzite rocks and Silurian slates, we come to Kilberg, about ten miles south, and two miles inland. There is a hill about 500 feet high, but although this would be only five or six miles north of the central line, it is not in other respects a desirable station. Steaming south-south-west we pass Store Ekkero, a promontory some twenty-five or thirty miles west of Vadso, which appears to have all the attributes of a good station, provided accommodation can be arranged for: the central line of totality passes over the southern point, and there is a free view to the south-south-east and east-north-east, the sun's azimuth at the local time of 18h. being 97° south towards east, and the duration of totality a maximum—viz. over 1m. 41s., the sun's altitude about $14\frac{1}{4}$°. Passing on to Vadsö, the town of the Finmarken district, there are several hills, two or three hundred feet, easily accessible, and in all respects suitable for observing stations within three or four miles; indeed, Vadsö should be looked upon as the headquarters of an East Norway expedition. The local time of totality here would be 17h. 57m. 46s., and duration about 1m. 35s. All the aforementioned places are in telegraphic communication with most parts of Norway during the fishing season, and no doubt arrangements could be made for keeping the offices open as late as August 8. The temperature at Vadso is remarkably high, probably between 50° and 60° F. in August, and there is every chance of fine weather at that time.

Crossing the Varanger Fjord we come to Bugö, a Lapp fishing station, and within a mile and a half of the central line; the longitude is about 29° 50′, and latitude 69° 58′. There the duration would be about 1m. 40s., with nothing to obstruct the view; frequent communication could be had with Vadsö at certain times of the day; heliograph signals might be transmitted; there are several sites hereabouts, but one in particular desirable. The Bugönæsfjeld I will leave to those who like to be in the clouds! So little is known of it that every map shows it in a different position; but if intrepid mountaineers are fond of carrying half-hundred-weights up mountains, there is no reason why they should not have the satisfaction they desire, but they will find no one to do it for them.

In order to distribute the parties and multiply the chances of success, one party might proceed from Vadsö to Seida, on the Tana River. This station is a good one for all points except the length of totality, which is only about 1m. 12s., and has the sun at an altitude of about $13\frac{1}{2}$°. Polmák, some twelve miles due south (reached by poling up the river), is not so easily got at, but astronomically better situated, and south-east of it, about five miles, is a mountain over 1000 feet high. About forty or fifty miles further up this river, in a south-west direction, is Utsjoki, a place also that might be advantageously occupied in the Russian Lapland. The duration of totality there would be about 1m. 26s., and the sun's altitude about 13°; both at Polmák and Utsjoki camp equipage would have to be taken. Both are in telegraphic communication with Vadso and Vagge, the latter place being at the mouth of the Tana Fjord. Karasjok is astronomically a good place, within four miles of central line, the sun's altitude being about $12\frac{1}{4}$° and duration of totality over $1\frac{1}{2}$m. Much, of course, will depend on the number of observers it is proposed to send out, their powers of endurance, and knowledge of Lappish, Russian, and Norwegian for the east coast expeditions (except at Vardo).

To the information which Colonel Burton-Brown has brought together, we may add that the Orient Steam Navigation Company propose to send one of their large steamships to Vadsö, for the purpose of enabling observations to be made of the eclipse. The steamer will leave London on July 21, and, after calling at Odde, Bergen, Naes, Molde, Trondhjem, Hammerfest, and North Cape, will arrive at Vadsö on August 3. It will leave a week later, and will arrive in London on August 17. (Full particulars of this journey will be found in our advertisement columns.)

We are informed by Messrs. Cook and Son that the Bergenske Steamship Company have consented, subject to certain conditions, to send one of their best steamers from Bergen and Trondhjem to Vardo and back, for the purpose of enabling persons interested in astronomy to view the eclipse. It is proposed that the steamer shall leave Bergen on July 31, calling at Trondhjem two days later, reaching Vardo on August 8, and remaining until 4 p.m. on August 9, returning to Trondhjem August 13, and Bergen August 15. The steamer will call at all the usual places visited by the tourist steamers between Bergen and the North Cape.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. Herman, of Trinity College, is appointed Chairman of the Examiners for the Mathematical Tripos.

The University Lecturer in Geography (Mr. H. Yule Oldham) announces a course of lectures on the Elements of Physical Geography during the present term. The Royal Geographical Society's Studentship of £100 will be awarded at Easter. Candidates must be members of the University who have attended the courses of the University Lectures.

The Council of the Senate recommend that the University of Allahabad be adopted as an affiliated University on terms corresponding to those in force for the University of Calcutta.

The report of the Syndicate on the Higher Local Examinations shows that good results have been attained in the scientific subjects. The new laboratory examination appears to work well, and has had a wholesome effect on the candidates' training.

Mr. W. C. D. Whetham and Mr. J. W. Capstick have been recognised as Teachers of Physics, and Mr. R. H. Adie as a Teacher of Chemistry, for medical degrees.

Among the freshmen who have matriculated this term, there are over 150 students of medicine.

SLOWLY, but surely, the system of paying teachers of elementary science according to the examinational successes earned by their students—in other words, according to their ability to cram young students with a large assortment of scientific facts, dogmatically stated and imperfectly understood—is giving way to one more calculated to create and foster a desire for natural knowledge. Within the past few days a Minute has been issued to schools under the Department of Science and Art, stating that the Lords of the Committee of Council on Education have decided to try the experiment of making grants for instruction in science and art depend partly upon the attendance of the student and partly on payments on results as tested by examination. The Committees of Science and Art Schools and Classes which have been in the receipt of grants from the Department for two consecutive years, or which are conducted by a local authority under the Technical Instruction Act 1889, or the Technical Schools (Scotland) Act 1887, will be allowed to elect to receive their grants on the scheme under which the payments on results will be one-half those on the present scale, while attendance grants will take the place of the other half, provided that the Inspector of the Department reports that the teaching and equipment of the school are thoroughly satisfactory, and that the class or classes are not too large for instruction by the staff of teachers. The attendance grant will be 1*d*. for each attendance of at least an hour's duration in a day science class, and 2*d*. in a night science class, and of 3*d*. for each attendance of one and a half hours' duration given to practical work in chemistry, physics, metallurgy, or biology, in a properly equipped laboratory. Applications to receive grants under the new Minute must be received before December 1, 1896, and in subsequent years before November 1. But the sanction to be so treated may be withdrawn at any time should it appear from the results of the examination in May, or from the reports of the Inspectors, that the instruction is not efficient; and no school can receive grants partly under the new Minute and partly under the ordinary scale of payments on results. Organised science schools are exempted from these attendance grants; nor can the grants be claimed on behalf of students who are on the register of an elementary school. The principle of recognising attendance at classes as one of the tests of the efficiency of a school has common sense at the back of it, and it should do something to reduce the baneful influence of the examination fiend upon elementary scientific education.

Dr. A. Rothpletz has been appointed Extraordinary Professor of Geology and Palaeontology in the University of Munich; Dr. Ernst Lecher, Professor of Physics in Innsbruck University, has been nominated to succeed Prof. Machs at Prague; Dr. F. Mares has been made Ordinary Professor of Physiology in the Bohemian University at Prague; and Dr. J. E. Humphrey has been appointed Lecturer in Botany at the Johns Hopkins University, Baltimore.

The Calendar of the University College, North Wales, for the year 1895-96, has been received. The physical, chemical, and biological laboratories (plans of which are given in the Calendar) now cover an extensive area. Under Prof. Andrew Gray, the physical department has greatly developed; and the appliances and electrical installation with which it is equipped enable the College to offer a complete course of instruction in all branches of electro-technical education.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 14.—M. Janssen in the chair.—The decease of Baron Larrey, free member, was announced from the chair. He died on October 8. M. Emile Blanchard pointed out the great influence of the deceased in modern surgery.—The Prince of Monaco has sent to the Academy No. ix. of his publications concerning the scientific work done on his yacht: a contribution to the study of the Cephalopods of the North Atlantic, by M. Louis Joubin.—On a mechanical amplification of the horizontal component of the earth's rotation, by M. Jules Andrade.—On a hydraulic apparatus to show the movement of rotation of the earth, by M. Aug. Coret.—M. Aug. Fabre, in a memoir on "Integration of the equation to the derived partials of the first order, of a function x with n independent variables $x_1, x_2, x_3, \ldots, x_n$" gives a quick new method of arriving at the general integral of an equation $\mu(x, x_1, x_2, \ldots, x_n, p_1, p_2, \ldots, p_n) = 0$.—M. J. Janssen, in the name of the Bureau des Longitudes, presented the 1898 volume of "Connaissance des Temps." There has been added to the tables concerning the satellites of planets, a table giving the elements for the calculation of the position of Mars' satellites at any given moment. In the ephemerides of the fundamental stars, the brightness of those above the first magnitude has been given, taking Aldebaran as unit. The Perpetual Secretary announced to be printed in the Correspondence, "Theorie der endlichen Gruppen von eindeutigen Transformationen in der Ebene," by M. S. Kantor.—On a class of linear equations to the derived partials, by M. H. von Koch.—On the surfaces of which the lines of curvature form a network with equal tangential invariants, by M. A. Thybaut.—On the double elliptic refraction and the tetrarefringence of quartz near its axis, by M. G. Quesneville.—On the estimation of argon, by M. Th. Schloesing. An apparatus with circulating mercury pump is described, which allows of the absorption of nitrogen and measurement of the residual argon. The whole arrangement is a modified form of Ramsay's apparatus for isolating argon.—On the action of hydrochloric acid on copper, by M. R. Engel. Copper decomposes a saturated solution of hydrogen chloride at 15° C., with liberation of hydrogen. This interaction does not occur if the concentration be less than that shown by the formula $HCl.10H_2O$. The presence of cuprous chloride retards the reaction greatly.—Action of potash and potassium ethoxide on benzoquinone, by M. Ch. Astre.—On combinations of antipyrine with the diphenols, influence of the respective positions of the hydroxyl groups, by MM. G. Patein and E. Dufau. Pyrocatechol, resorcinol, and quinol (hydroquinone) behave differently with regard to antipyrine: the ortho- and para-diphenols combine with two molecular proportions, the meta- with one. The combination occurs through one of the nitrogen atoms and the phenolic hydroxyl, which loses this property when its hydrogen is replaced by a metal or radical.—Experiments on the reducing power of pure yeasts, means of measuring it, by M. Nastukoff.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Elements of the Mathematical Theory of Electricity and Magnetism: Prof. J. J. Thomson (Cambridge University Press).—Elementary Physiography: Prof. J. R. A. Davis (Blackie).—A Directory of Science, Art and Technical Colleges, Schools and Teachers in the United Kingdom: R. L. Lawrence (Chapman and Hall).—A Manual of Physiology: Dr. G. N. Stewart (Baillière).—Movement: E. J. Marey, translated by E. Pritchard (Heinemann).—Frail Children of the Air: S. H. Scudder (Boston, Houghton).—Darwin and after Darwin: Dr. G. J. Romanes, ii (Longmans).—Among Rhode Island Wild Flowers: Prof. W. W. Bailey (Providence, R.I., Preston).—Pagan Ireland: W. G. Wood-Martin (Longmans).—First Steps in Egyptian: Dr. E. A. W. Budge (K. Paul).—Birdcraft: M. O. Wright (Macmillan).—Fishes, Living and Fossil: Dr. B. Dean (Macmillan).—Science and Art Drawing: J. H. Spanton (Macmillan).—Great Astronomers: Sir R. S. Ball (Isbister).—Elektrophysiologie: Prof. W. Biedermann, Zweite Abthg. (Jena, Fischer).—Protobasidiomyceten: A. Möller (Jena, Fischer).—The Tallerman-Sheffield Patent Localised Hot-Air Bath (Baillière).—University College of North Wales, Bangor, Calendar for the Year 1895-6 (Manchester, Cornish).—Atlas d'Ostéologie: Prof. C. Debierre (Paris, Alcan).—Evolution and Effort: E. Kelly (Macmillan).—A Handbook of British Lepidoptera: E. Meyrick (Macmillan).—Surface Currents of the Great Lakes: M. W. Harrington, revised edition (Washington).—Annuario p.p. Observatorio do Rio de Janeiro, 1895 (Rio de Janeiro).—U.S. Geological Survey Report, 1892-93, 2 parts (Washington).

Pamphlets.—Neue Versuche zum Saison-Dimorphismus der Schmetterlinge: Dr. A. Weismann (Jena, Fischer).—Neue Gedanken zur Vererbungsfrage: Dr. A. CONTENTS.

THURSDAY, OCTOBER 31, 1895.

THE CENTENARY OF THE INSTITUTE OF FRANCE.

FROM the brief telegraphic reports published in some of the English newspapers, readers in this country may have observed that the hundredth anniversary of the foundation of the Institut de France was celebrated last week in Paris. These reports, however, convey but a feeble impression of the real character of the celebration. The Institute is an establishment of which Frenchmen of all classes and of every shade of political opinion are justly proud. They look on it as a living embodiment of the culture and intellectual power of France. It stands above and beyond politics. Forms of Government may come and go; kings, emperors, and republics may arise, flourish, and disappear. But the Institute remains unshaken, quietly pursuing its career, and sustaining with marvellous success the intellectual glory of the nation. No wonder, then, that amid the turmoil of parties, the strifes of Parliament, and the endless changes of Ministries, many men turn to the Institute as the only stable institution, which royalists, republicans, socialists, and anarchists seem to be alike agreed in respecting.

That Republicans especially should show an interest in this institution was natural. It was founded a hundred years ago during the first Republic. The idea of restoring the old Academies and combining them into one central institution was carried out by the Republican Convention, with the openly professed intention of promoting the literary, artistic and scientific labours which should best contribute to the general benefit and glory of the Republic. After all the transformations of the last hundred years, a Republican form of government is once more in power. It was only fitting, therefore, that the State, by its highest officials, should manifest its interest in this, the oldest and most illustrious child of the Revolution, by taking an active and prominent part in the Centenary of its existence.

An Englishman privileged to be present at the celebration could not fail to be struck by various features in it that stood out in marked contrast to anything that would have been possible in his own country. In the first place, of course, the Institute itself is unique, in the wide range of subjects with which it is concerned. We have many admirable learned societies at home, from the Royal Society downwards, and so far as scientific progress is concerned, they are possibly of at least as great service as any Academy of Sciences in the world. We have likewise our Royal Academy of the fine arts, which may, it is to be hoped, hold its own against any foreign competitor. We have, however, nothing that corresponds to the French Institute, and the question has often been discussed whether the creation of such an Institute amongst us would be possible or desirable. But what especially strikes a stranger at such a gathering as that of last week in Paris, is the catholicity of view which led to the union under one organisation of so vast a range of human culture and faculty. Prose-writers, poets, dramatists, antiquaries, mathematicians, physicists, astronomers, geographers, engineers, chemists, mineralogists, geologists, botanists, anatomists, zoologists, physicians, surgeons, painters, sculptors, architects, engravers, musicians, writers on philosophy, morals, law, political economy, and history—all meet as in a common home under the dome of the Institute on the banks of the Seine. Each of the five Academies has its own sphere of activity and its own independent organisation. But they confer mutual strength and dignity on each other by the common tie that binds them together as the Institute of France. And one cannot help feeling that in a country liable to such political vicissitudes as France has gone through during the last hundred years, it has been of unspeakably great advantage to the stability and progress of all the arts and sciences which elevate a people, that this solidarity of intellectual effort should have been established at the beginning of the long succession of political troubles.

Another feature which impressed a native of this country was the direct, hearty and effective part which the highest functionaries in the State played in the chief events of the celebration. The President of the Republic himself received the foreign members and correspondants one morning at the Elysée, shaking hands with each, and stopping every now and then to say some few appropriate words to one whose name or whose work was known to him. The whole ceremony was as simple and natural as it was pleasant. M. Faure likewise presided at the opening meeting at the Sorbonne; and on Friday evening he held a brilliant reception, to which all the members and correspondents of the Institute were invited, with their wives, together with a large assemblage of other guests, including the Ministry, the Diplomatic Corps, and representatives of the chief departments and institutions. In short, everything which the head of the State could do to testify officially the pride and interest of France in her Institute was done simply and heartily. One felt that the President, kindly and gracious as he was personally, represented a national feeling which would have demanded expression no matter what form of Government had been in existence, or what political party had been in power.

Nor was the action of the President the only manifestation of official interest in the celebration. The Prime Minister, the Ministers for Foreign Affairs, War, Marine, Public Instruction, and others found time to spend an hour or two at one or other of the gatherings. The Minister for Public Instruction, M. Poincaré, indeed, multiplied himself in the most astonishing way. Having the official control of the department under which such organisations as the Institute are placed, he evidently considered it to be his duty, as it seemed certainly to be a pleasure to him, to attend every gathering where his presence could testify the sympathy of the Government with the Institute and its objects. At one time he was to be seen at the Ministry of Public Instruction holding a reception of all the academicians and correspondants, with their wives, and a large company of representative men from outside. At another time he was on the platform beside the President, making a vigorous speech, and conveying to the Institute the appreciation which he and his colleagues had of the work which the various Academies had accomplished. Again he was in his place presiding at the banquet given to the Institute, ready once

more with eloquent words to wish prosperity to literature, art, and science. And as if all this were not enough in the midst of his other busy official engagements, we found him just after breakfast at the unveiling of the Meissonier statue in the Louvre Gardens, where he made an admirable speech, summing up the characters of Meissonier's work.

An Englishman might be forgiven if he ventured to express openly his opinion that such things as these could not, or at least would not, be done in his own country. We suppose our Vice-President of the Council is the Minister who most nearly corresponds here to the Minister of Public Instruction in France. But when had we ever a Vice-President who thought it worth his while to show, outside of his official duties, so much active interest in the cause of science, art, and literature?

While this recognition from the State and its functionaries was extended to the Institute, the latter showed in several ways how well it realised its representative character as the outward symbol of the higher intellectual progress of France. One was especially impressed by the way this feeling was exhibited at the opening gathering in the great hall of the new Sorbonne. Behind the academicians and correspondants, the best seats in the building were allocated to representatives of education, law, justice, &c. The chief schools and colleges had places allotted to them, legibly marked out by large labels affixed to them. Lawyers, judges, and professors came in their robes to take part in the proceedings. Every section of the programme appeared to have been most carefully thought out. There was a well-trained orchestra, which began by playing a composition of the first composer who became a member of the Institute of France, and afterwards gave a fragment of *Mors et Vita*, by Gounod the last composer who had passed away from the Academy of the Beaux-Arts. Good care, indeed, was taken in the celebrations to show that music and the drama were included within the range of the Institute's activities. An afternoon "gala" performance at the Théâtre Français included parts of Corneille's *Cid* and Molière's *École des Femmes* and *Femmes Savantes*, wherein the chief members of this incomparable company showed once more what perfect acting should be.

Lastly, a stranger could not but be pleased with the numerous facilities offered to him to meet his old friends, and to make new ones. At the evening receptions and dinners, at the daylight gatherings in the Institute buildings, and in the foyer of the Théâtre Français, but most of all in the excursion to Chantilly, and the rambles through the rooms and grounds of that princely chateau, he had opportunities of seeing everybody that he wished to converse with. No one who went to Chantilly will be likely to forget the success of that concluding day of the proceedings the autumnal woods with their long vistas, the magnificent castle, the endless treasures of art and literature within the rooms, but above all, and as the centre and soul of the whole scene, the figure of the Duke d'Aumale, who has gifted all that estate to the Institute. Sitting in his bath-chair wrapped up in black velvet, hardly recovered from his last attack of gout, he showed himself the most vivacious talker in the company, shaking hands with his guests, discoursing to them of pictures, travel, and incidents of his life with the urbanity and dignity of the old *grand seigneur*.

There was one special source of gratification to English visitors in the remarkable band of men who went to represent Great Britain at the Centenary. The French members of the Institute seemed to feel the compliment paid to them by the attendance of so many illustrious men of science, literature and art. And the strength of the English contingent drew forth the admiration of visitors from other countries. It was pleasant, in these days of political rivalry, to see human culture linking men in a brotherhood which stands above nationality and politics, and more especially to note that nearly the whole of the Englishmen who have been so generously recognised by the Institute of France should have attended its Centenary.

THE GOLD MINES OF THE RAND.

The Gold Mines of the Rand; being a Description of the Mining Industry of Witwatersrand, South African Republic. By F. H. Hatch and J. A. Chalmers. London: Macmillan and Co., 1895.

AFRICA is proverbially a land of surprises. It is not likely, however, that more startling surprises can be in store than those witnessed by the present generation. We have seen a great city spring up, in what, before the discovery of gold in the Witwatersrand, was a desert, a city with over eighty mines, the workings of which extend east and west from Johannesburg for 45·8 miles. The mines have been worked with regularity, and the augmentation of dividends has attracted the attention of capitalists in all parts of the globe, resulting in the Russian Government commissioning Mr. Kitaeff to report on the gold-field, and in the Prussian Government despatching Mr. Schmeisser for the same purpose. The output of gold from the Witwatersrand has risen from 23,000 ozs. in 1887 to 2,023,198 ozs., valued at nearly £7,000,000, in 1894, whilst the return for the first nine months of the current year was 1,711,337 ozs. The Transvaal now produces one-fifth of the world's supply. It is calculated that at the present rate of progress the output of the Witwatersrand mines will have reached by the end of the century a value of £20,000,000.

To the already ample literature relating to the Transvaal gold mines, this handsome and profusely illustrated volume of three hundred large octavo pages is the most valuable contribution that has yet appeared. The authors possess special qualifications for the important task they have undertaken. Mr. J. A. Chalmers is an Associate of the Royal School of Mines, and his brilliant career as a student has been followed by many years successful practice as a mining engineer in South Africa; whilst Dr. F. H. Hatch's scientific attainments and literary skill are well known from his important petrographical researches carried out previously to his retirement in 1892 from the Geological Survey of England and Wales, and from his useful manuals on mineralogy and petrology.

The authors divide their subject-matter into twelve chapters. The first deals with the history of the gold discoveries and of the development of the mining industry, whilst the subsequent chapters deal respectively with the geology, the auriferous conglomerates, the

Witwatersrand deposits, the development and prospects of deep-levels, mining practice, surface equipments of the mines, the metallurgical treatment of the ore, economics, mining law and statistics.

Unfortunately for students of South African geology, much confusion results from the fact that beds of an identical character often receive different names in different localities. The inconvenience of this want of uniformity in the classification of the rock systems will now, it is hoped, be obviated, as the authors' clear exposition of South African stratigraphy cannot fail to be generally accepted. The geology of South Africa is, it may be noted, comparatively simple. The main subdivisions are (1) recent deposits; (2) the Karroo formation; (3) the Cape formation, and (5) the South African primary formation. The sedimentary deposits are underlain by granites, gneisses, and crystalline schists, which constitute the greater portion of the formation of north-west central Africa. This primary formation occurs largely in Mashonaland, Matabeleland, and the Mozambique, and predominates in the northern and eastern parts of the Transvaal. Lying unconformably on these beds are the shales, sandstones, conglomerates and limestones of the Cape formation, which extend over the southern, western, and middle parts of the Transvaal. They appear to be of an age corresponding with the Devonian and Lower Carboniferous periods of European classification. The Karroo formation, which may possibly be correlated with European Lower Mesozoic formations, has a widespread occurrence in Cape Colony, Natal, the southern Transvaal and the Orange Free State. It derives its importance for the Transvaal from the fact that it carries the coal-seams that have rendered such valuable aid to the development of the auriferous deposits. Lastly, the recent deposits comprise those of alluvial and æolian origin, together with the curious surface material to which the authors apply the somewhat misleading name of "laterite." This material is widely distributed throughout the Transvaal. The gold of the Witwatersrand is obtained entirely from beds of conglomerate, known as "banket," carried by the Cape formation. These are composed mainly of pebbles of white or grey quartz embedded in a matrix consisting originally of sand, but now completely cemented to an almost homogeneous material by a later deposition of quartz. The pebbles as a rule do not carry any gold, the mineralisation being confined to the matrix. The average total yield of the conglomerate stamped last year was 13·16 dwts. of fine gold per ton. With regard to the origin of the ore-bodies, the authors enumerate the various hypotheses without giving their support to any one of them. They have, however, been unable to find any evidence in favour of the idea locally prevalent that the dykes met with, have acted benefically on the banket in their immediate neighbourhood in regard to gold contents. Petrologically the dykes belong to the group of dark-coloured greenstones, among which the authors have recognised the following types: diabase, olivine-diabase, bronzite-diabase, epidiorite, gabbro and olivine-norite.

One of the most interesting chapters in the book is that on the development and prospects of deep-levels. As the bedded character of the banket deposits became known, and as the persistency in depth and the uniformity in the gold-contents became established by deep boreholes, companies were organised to work the deep-seated portions of the beds. In discussing the depth at which the main bed will be found, the authors bring forward evidence to show that a very important flattening of the bed takes place. They therefore take a more optimistic view of the future of the gold-mining industry than that taken by other writers. The most important problem that presents itself is to ascertain the limit in depth to which mining may profitably be carried. The limiting factors are increased temperature, excessive initial expenditure, and increase of working costs. The rise in temperature with increasing depth must, the authors think, be ascribed almost entirely to secular causes. Unfortunately very few experiments have been made to gauge the rate of increase. Mr. Hamilton Smith in 1894 made some determinations of the water in the Rand Victoria borehole at a depth of 2500 feet, the results indicating an increase of 1° F. for every 82 feet. Some rough determinations, too, have been made by Mr. A. F. Crosse at the Ferreira and Crown Deep shafts. In view of the scientific interest and commercial importance of the matter, it is to be hoped that an accurate determination of the temperature will be made at the bottom of the borehole which is now being put down to intersect the main bed at a depth of 3500 feet. At present, experience in other countries is the only available guide, and it is to be regretted that such results collated by the authors are very incomplete. A table of temperatures in some deep European and American mines is given (p. 104), but this, being disfigured by gaps and misprints, such as St. Andre for St. Andreasberg, Prizebram for Przibram, Sanson for Samson, Lambert for Charleroi, does not carry much weight. Nor are the shafts of the Michigan copper mines fair illustrations to select, inasmuch as the coolness of the rock is undoubtedly due to the proximity of the cold waters of Lake Superior. The authors' statement that at the Calumet and Hecla shaft, Michigan, there is a rise of only 4° F. in a depth of 4400 feet, is certainly inaccurate. The temperature determination must have been influenced by the fact that compressed-air rock-drills are in use at that mine. The ice-cold exhaust would lead to erroneous results. The usual geothermic gradient is 50 to 55 feet for an increase of temperature of 1° F., and the lowest recorded is that of 100 feet to 1° F., at the Lake Superior copper mines. It would appear, therefore, that in assuming it to be somewhat less than this in the Rand, the authors are taking too optimistic a view, more especially as Mr. Crosse's determination (p. 103) of 66·7° F. at 825 feet, and 70·7° F. at 1030 feet, indicate the normal gradient of 50 feet to 1° F. In the discussion of this important subject, the authors might have referred with advantage to Koebrich's 387 determinations of temperature in the Schladebach borehole. These are of special importance, as they were taken at fifty-eight points at equal distances of 30 metres down to the greatest depth yet attained of 1716 metres. The result of this investigation was that the gradient was found to be 46·09 metres for 1° R.

The chapters describing mining practice, surface equipment, and the metallurgical treatment of the ore, occupy more than a third of the volume. Admirably illustrated by

excellent drawings and photographs, they give a clear idea of the vigorous manner in which the work is carried on. Additional authority is given to them by the fact that they contain contributions by Mr. L. I. Seymour, Mr. C. Butters, and other leading engineering experts. The volume concludes with valuable information regarding material and supplies, labour, working costs, mine accounts, mining laws and regulations, production and dividends. A good index, eighty illustrations, fourteen photographic plates, and seven folding maps and plans, complete a volume of which the authors may justly be proud. With the exception of a geological map, which would have been a useful addition, the only omission appears to be a bibliography of the existing literature relating to the subject. The authors appear to be unacquainted with the geological work of Mr. C. J. Alford (London, 1891), and with the engineering descriptions of Mr. T. Reunert (London, 1893). Indeed they regard the published information relating to the nature of the ore deposits and to the extraction of the gold as meagre and inadequate. Yet Mr. W. Gibson in 1892 published a list of sixty-seven works on South African geology, sixteen of which bear directly upon the geology of the Transvaal. Mr. Schmeisser in 1894 gave the titles of fifty such works, and Dr. K. Futterer in 1895 gave 156 titles. With the rapid development of the mining industry, literary productions become antiquated with remarkable rapidity. When the writer of this review visited the Witwatersrand in 1892, there were 1907 stamps running. Now, according to Dr. Hatch and Mr. Chalmers, there are 2642 (June 1895). Since 1892 work has been pushed on more vigorously than ever before, and from the sixty mines near the outcrop of the main bed 5,000,000 tons of ore have been extracted in 1893 and 1894. Numerous deep boreholes have been put down to the dip of the bed, and several shafts have been sunk, encountering the auriferous conglomerates at depths of 600 to 1000 feet. Five years hence there will be 8000 stamps running. The present average stamping capacity is over four tons per stamp per day, and it is probable that, owing to technical improvements, the average will be five tons. With a total extraction of 10 dwts. of gold per ton, the output should be 6,500,000 ounces. The ore reserves are estimated at 170,000,000 tons, equal at 45s. per ton to £382,000,000. It seems unlikely that the average cost of mining and treating this ore will exceed the present cost of 30s. per ton. The authors think, therefore, that they may safely forecast a production from the Witwatersrand within the next half-century of £700,000,000, of which £200,000,000 will be profit.

Bennett H. Brough.

STARCH.

Untersuchungen über die Stärkekörner. By Dr. A. Meyer. (Jena: Fischer, 1895.)

THOSE who are best acquainted with the laboured details of Naegeli's classical investigations into the nature and growth of starch-grains, and the controversy which followed regarding his astounding hypothesis, which so long dominated certain of our text-books under the name of the "intussusception theory," will best be prepared for another huge work of inquiry into the physical and chemical nature, growth and solution, and significance to the plant generally of those curious structures. The full appreciation of the magnitude and value of Meyer's task will depend on the reader's acquaintance with the bearing of numerous discoveries which have been made since Naegeli's day, and turned to criticism and the final overthrow of his hypothesis; and among these stand prominently, on the biological side, Schimper's demonstration of the significance of the various plastids to the stratification of the starch-grain, Sachs' brilliant work on the *rôle* of the starch-grain in assimilation, and Strassburger's severe criticisms in his researches on the structure and growth of the cell-wall; and, on the physical and chemical side, Émil Fischer's work on the synthesis of carbohydrates, and the splendid work of our own countryman Horace Brown—the latter, indeed, as much physiological as chemical in its methods and results.

Meyer's book, which contains over 300 large pages of closely-printed German in the dryest of styles, which would be hard to forgive if the matter were not so good and the spirit so enthusiastic, covers the whole range of the enormous domain now centred around this formerly so insignificant a structure, the starch-grain; and it is embellished with nine tables and ninety-nine illustrations, good, bad, and indifferent, for the quality of the figures varies much, suggesting periods of different powers or methods of delineation during the fifteen years or so the author has been occupied with this monumental monograph.

For it *is* monumental, in the sense that it has evidently been gradually built up as a big structure, bit by bit, with morsels of hard evidence dug with great labour from the difficult quarry of facts, only to be worked with the best powers of the microscope, and the best methods which modern technique puts at the disposal of the investigator.

The work may be regarded as divided into five parts. The chemistry, physics, and biological properties of the starch-grain as an object of research, form the subject-matter of three of these parts; the fourth is occupied with some extremely ingenious and careful comparative studies of the changes undergone by the grain in the different organs of various selected plants, at stated seasons, and under experimentally varied conditions; while the fifth part may be taken as the critical survey of the investigations and views of others scattered through the body of the work, and the copious literature collected at the end.

It is, of course, impossible to traverse a work like this in a review, and the following short summary must suffice for a glimpse at Meyer's views and results, some of which he has already published in short papers from time to time.

He regards the typical starch-grain as consisting of two substances, one of which, *a-Amylose*, can be obtained separately in the crystalline form, whereas the other—*β-Amylose*—cannot be isolated in crystals. The relations of these two constituents to each other, and to other carbohydrates found in modified starch-grains, are considered in detail; they occur in the grain itself as acicular crystals (*trichites*) arranged more or less radially, and the starch-grain is in effect nothing but a complex, mixed sphere-crystal composed of radiating branch-systems of these *trichites*, in different proportions, and more crowded in the denser layers than in the softer ones.

The cases where amylo-dextrine occurs, and the relations of all these substances to other carbohydrates, their behaviour in water of various temperatures, the action of diastase, and so forth, are discussed at great length, and we are glad to see that the author has paid attention to, and, it may be added, been considerably influenced by, the valuable work of Brown, Heron, Morris and Salomon, and there are points of discussion of interest to all these workers.

Of course a view like Meyer's must depend for its validity essentially on what experimental results can be got in the way of obtaining sphere-crystals of carbohydrates like amylose under known conditions: if the author's statements regarding the crystallisation into spherites of inulin and amylodextrin and other bodies in a viscous matrix can be extended to the case in point—where the protoplasm of the amyloplast acts as the viscous matrix—he has certainly made out a strong case, for all the ordinary physical properties of porosity, behaviour to polarised light, swelling, and the stratification, striation, and other structural peculiarities of the starch-grain are as easily explained if the unit of structure is a *trichite* as where it is assumed to be a *micella*.

Since it is as yet impossible to artificially crystallise the amylose composing the chief part of a normal grain, into the spherical shape, however, the war of discussion will no doubt rage around this point; in the meantime, Meyer has unquestionably marshalled his facts in heavy order and made out an ingenious case, the full significance of which can only be grasped by ploughing one's way through his heavy, but, in the main, logical German.

The phenomenon of swelling has always been a crux in hypotheses regarding the structure of organised bodies. Meyer explains it as due to the *trichites* of β-*Amylose*—the principal constituent of the normal starch-grain—absorbing water, and themselves swelling. In other words, the water dissolves in the crystals.

It should be noted, however, that Meyer distinguishes sharply and emphatically between *Porenquellung*, where water is merely imbibed between the crystals, and *Lösungsquellung*, where the water is taken up by the crystals; and he here emphasises what may be a useful distinction in questions of imbibition. It is, of course, *Losungsquellung* which initiates the disorganisation of the grain.

In the discussion of the question as to the growth of the starch-grain, the author points out that the latter may grow in chromoplasts, as well as chloro- and leucoplasts, and that the grain *never* impinges on the cytoplasm—it is always completely surrounded by a layer, however thin, of its plastid so long as the cell lives; he makes this seem probable, but it is impossible to prove it in some instances. In any case, the reader will find some pretty staining methods brought to bear on the point.

Of course the grain grows by apposition, and the thickness of the layer deposited depends on that of the protoplasm in contact at the place. On the whole, indeed, the laws of growth and stratification are those laid down by Schimper and Strassburger, though Meyer adds a good many facts as to the initiation and growth of both simple and compound grains, and has devised a new nomenclature and classification of the various kinds of starch-grains which, complete and exhaustive though it appears, we confess does not seem to meet the requirements of clearness and simplicity so fully as could be desired.

One of the most ingenious chapters in the book is that on the solution of the grains in the cell, and the significance of fissures and pores for the attack of the diastatic or other solvent.

Space is not available for detailed remarks on the author's methods of examining the changes which the starch-grains undergo in the various organs of *Adoxa*, *Hordeum*, *Dieffenbachia*, *Pellionia*, *Hyacinthus*, *Oxalis*, &c., at different times of the year and under different conditions; nor to give his views on the constitution of protoplasm—which we venture to think too much of the nature of a hastily-written note, moreover not necessary to the subject, and far from convincing in the six pages (with critical sentences on everybody from Naegeli and Wiesner to Bütschli interspersed) devoted to it. Put briefly, Meyer regards protoplasm as a peculiar emulsion, and therein agrees essentially with Berthold; whereas the elements of cell-walls and starch-grains are as truly crystallised out as is calcium oxalate.

The experiments showing that the position of the layers of the starch-grains can be altered by changing the position of the organ in which they are growing, and that the alternation of day and night is expressed in the thickness and density of the layers—that the layers are "diurnal layers"—in effect (pp. 268–271) are well worth attention, however, as indeed are very many others of the difficult experimental points brought out towards the end of the book.

That the questions centering around the starch-grain have not reached finality, is obvious, but that Meyer has contributed a valuable attempt to set some of them at rest, must be admitted by all who read his monograph. It bristles with debatable points, and there are some annoying faults—*e.g.* the frequent references to figures and titles in the text without sufficient clues, and to chapters ahead of the reader; but that does not weaken the fact that his results stimulate the reader to some close thinking, and his critical compilation of the history and literature of the subject alone makes the book necessary to all working botanists.

H. MARSHALL WARD.

APPLIED METEOROLOGY.

Weather and Disease. A Curve History of their Variations in Recent Years. By Alex. B. MacDowall, M.A., F.R.Met.S. London: The Graphotone Co., 1895.

THE systematic study of climatic conditions in connection with the fluctuation in the public health, is one which has only recently been undertaken, but which already promises results of a most interesting and important character. Apart from the inherent interest of the subject, which must indeed be apparent; the study offers, like observations in phenology, the prospect of great practical value. The work of weather forecasting is at present so wanting in accuracy, and there is so little promise of progress in this direction, that practical meteorologists might be tempted to despair, and the general public be led to imagine that the vast stores of records which have been accumulated were destined to

remain fruitless for an indefinite time. The application of meteorology to related subjects in general, and to hygiene in particular, may thus be considered doubly welcome.

Mr. MacDowall's primary object, in the publication before us, is to represent the variations which certain elements of the weather, and the mortality from certain common diseases have undergone during recent years, and it may be to find a connection between the two. The mode of representation which the author has adopted is the one now commonly in use of plotting curves on ruled paper, by adjoining points, the ordinates of which are determined by the two quantities to be related, one of which generally refers to date. These curves have as a rule been subjected to a process of *smoothing*, which, by recording the average of every five or ten (as the case may be) consecutive values, eliminates the fluctuations of short duration, while preserving the more gradual and lasting variations. The great advantage which this method possesses is, it is hoped, to enable the eye at once to detect the more salient features of a general tendency, without the mind being distracted by a mass of details which may be, for the purpose in view, absolutely useless. In this way, within the compass of some twenty curves, the author exhibits the general tendencies which have controlled the principal and most interesting features of the weather; while a further sixteen curves show the fluctuations which have taken place in the most important zymotic diseases.

If we have any fault to find with a very excellent purpose, on the whole admirably carried out, it would be to remark that the curves would be better if drawn on a larger scale. This would have increased the expenses of production, but the result would be clearer. It would have been of advantage, too, if the numerical details, from which the curves have been drawn, had been given; then any one interested in a particular inquiry could have easily constructed the curve to any desirable scale. This point is of particular importance if the reader wishes to know what is the "probable error" of any point on the smoothed curve, or, in other words, what is the degree of reliance to be placed upon the process of smoothing. For instance, a comparison is instituted, or at least suggested (p. 63), between the curves representing the mortality from diarrhœa and dysentery, and that showing the mean temperature for July at Greenwich. There is apparently some resemblance between the two, but the probable error of either curve may be greater than this apparent agreement. If the solution of a system of equations of condition, to which these curves may be compared, yield the quantity sought, accompanied by a probable error as large as the unknown itself, great hesitancy is experienced in accepting the result as a satisfactory solution.

Mr. MacDowall's aim is apparently a modest one: for the most part he is content to leave his graphic representations of both kinds of records to speak for themselves, and invite the reader to study them independently, and to follow up any point which they may suggest. The author's own notes are not copious, but they are clear, interesting, and concise. Some of the curves, too, are very instructive. The opponents to compulsory vaccination will not find much to support their views in the curve tracing the mortality from small-pox through the last two centuries. The steady and consistent improvement in the twenty years following the introduction of vaccination, in 1798, pleads eloquently in favour of the process. The great decrease shown in the number of deaths from scarlet fever may be misleading, if it be not compared with the sad and alarming increase in the mortality from diphtheria. Previous to 1859, these two diseases were not separately registered in the Registrar General's Reports; but if the two curves be combined, the mortality from neither has conspicuously varied.

The book, small as it is, appears to have been carefully compiled, and must have involved a considerable amount of labour in its production. It should certainly be consulted by those who are interested in the relations between meteorology and hygiene. W. E. P.

OUR BOOK SHELF.

Popular History of Animals for Young People. By Henry Scherren, F.Z.S. Pp. 376. (London: Cassell and Co., Limited, 1895.)

What would have been said a few years ago of a popular history of animals of which the opening chapters were devoted to man and his resemblance to other members of the Order Primates? In the days when it was the fashion to place man in a separate order of Bimana, while the man-like apes were called Quadrumana, the mere idea of including the human race in the animal kingdom would have raised a storm of indignation. Yet here we have a book, intended for a popular public, in which the principle of relationship is fully recognised, and man is assigned his proper place in nature. Thus do the scientific ideas which are anathema of one generation become the accepted truths of the next.

One of the features which distinguish this book from most of the legion of popular works on natural history published in recent years, is that common names of animals are used throughout, and no attempt is made to familiarise the reader with the nomenclature of scientific zoology. This fact will endear the book to all who like to learn a little about the habits of animals, but have no desire to know any details. For such readers the present volume is admirably suited; it is full of readable anecdotes about animals, and is illustrated with thirteen coloured plates, as well as numerous figures in the text. Most of the illustrations, both coloured and plain, are old friends, but a few have been reproduced from photographs. We think the volume will be successful as a prize-book and as a book for general readers.

Simple Methods for Detecting Food Adulteration. By J. A. Bower. Pp. 118. (London: Society for Promoting Christian Knowledge, 1895.)

The author describes a number of simple tests for detecting common adulterations in articles of food. In the main, the tests described can only be carried out by means of a fairly good microscope, so they are quite beyond the ordinary householder until he provides himself with such an instrument, and educates himself in the use of it. Of the thirty-six illustrations in the book, twenty-eight represent microscopic views of various substances, and it will be of little use for any one to set about detecting fraud until he is perfectly familiar with the varying appearances exhibited not only in the illustrations, but by actual specimens mounted on slides. Possibly the book will induce young people to determine specific gravities, and make other simple observations; and if it does that, it will justify its existence.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Introduction of a West Indian Frog into the Royal Gardens, Kew.

A SHORT time ago Mr. W. Watson, the Assistant-Curator of Kew Gardens, informed me that he had noticed for several years, in some of the hot-houses, specimens of a small frog, which, hiding away during the day among the pots and orchid-baskets, enlivened the quiet evenings with their shrill, whistling notes. Suspecting that this frog must be a foreign importation, I asked the Director to allow some of the specimens to be caught, and some days ago I had the pleasure of receiving three specimens in excellent condition.

The frog is *Hylodes martinicensis*, a small arboreal species, distributed over, and common in, many West Indian Islands (Martinique, Porto Rico, St. Vincent, Dominica, Barbadoes, &c., and possibly in Trinidad). Mr. Watson recollects that he observed it first some ten years ago, that he lost sight of it for some time, but that it reappeared about four or five years ago. Taking into consideration the few facts with which we are acquainted as to the reproduction of this frog, it seems most probable that several specimens of both sexes were, on more than one occasion, accidentally introduced in Wardean cases.

However that may be, it is evident that the frogs have freely propagated since their introduction. At present they are most numerous in the propagating houses, in which the temperature ranges between 80 and 100°, sinking in winter at times to nearly 60°. Accompanying Mr. Watson one evening, I heard from several points the call of the frogs, which somewhat resembled the piping of a nestling bird; and guided by the sound, I had soon the pleasure of seeing one of them clinging to the side of a glass-case.

There is nothing extraordinary in the accidental importation of individuals of a tropical species of frog into Europe; but it is an interesting experience, that the species should have permanently established itself. This is owing, in the first place, to the favourable conditions under which it found itself placed, and, secondly, to the peculiar mode of its propagation.

Hylodes martinicensis, and probably the majority of its congeners, does not spawn in water, but deposits from fifteen to thirty ova on leaves in damp places. After a fortnight the young frogs are hatched in a perfect form, having passed through the metamorphosis within the egg, thus escaping the vicissitudes and dangers to which they would have been exposed during the progress of the usual Batrachian metamorphosis.

This instance of the acclimatisation in Kew Gardens of the "Coqui" (as the frog is called in Porto Rico) is unique in Batrachian life at present. I trust that the little guest may long flourish where it has found such a congenial home, and where it usefully aids in the destruction of plant-eating insects and wood-lice, of which I found great numbers in the stomach of a specimen. If at a later period a nest with ova were discovered, Mr. Dyer would delight the heart of embryologists, to whom the opportunity of examining fresh ova of this frog would be most welcome. ALBERT GÜNTHER.

Kew, October 20.

The Cause of an Ice Age.

IT appears to me that the position taken up by Sir Robert Ball in his book, "The Cause of an Ice Age," is seriously misrepresented by Sir H. Howorth in one paragraph of the criticism which appears in NATURE of October 17. Sir H. Howorth says, that the fact of the invariability of the ratio of the heat received by our hemisphere in summer to that received in winter cannot be the cause of variability in climate; "if, as we are told in the book over and over again, this particular proportion (63 : 37) is the cause of the Ice age, we must be living in an Ice age now, and we must always have been living in an Ice age." Now it is nowhere asserted by Sir Robert Ball that the invariability or the magnitude of this ratio is the cause of an Ice age, but it is very clearly explained that he assumes the cause of an Ice age to be a *particular range of positions of the line of equinoxes combined with a high value of the eccentricity of the earth's orbit*, and that the fact that the above ratio is 63 : 37, and not unity, as appears to have been supposed to be the case, is relevant only so far as it inclines us to regard the changes of climate due to the causes just mentioned as much greater than we might otherwise have regarded them.

It seems obvious that a large value of the eccentricity contemporaneous with a favourable position of the line of equinoxes will correspond to *some change* in climate. Whether this cause is a dominant one, or even an important one, in its effect on climate, is of course an open question, and one upon which I express no opinion. Sir H. Howorth thinks that Sir Robert Ball has inadequately recognised the fact that the ratio of heat received in summer to that received in winter by one hemisphere has been calculated by Wiener. I find, however, on page 90 (second edition), the following reference to Wiener's work. "They depend on the mathematical calculation given for the first time, I believe, by Wiener in his work, "Zeitschrift der Oesterreichischen Gesellschaft fur Meteorologie," vol. xiv., 1879, p. 129. . . . My chief object is to emphasise the relation of these calculations made by Wiener to the astronomical theory." Wiener's work is also mentioned in the preface.

On the general question as to the adequacy of Croll's theory, with or without the fact which Sir Robert Ball adduces *solely* with a view of strengthening that theory, I express no opinion; it seemed to me, however, that in fairness, some of the remarks made by Sir H. Howorth required refutation.

Christ's College, Cambridge. E. W. HOBSON.

Green Oysters.

ONLY to-day I was able to read Prof. Lankester's letter (NATURE, May 9, 1895), and wish to reply briefly. My note in *Monitore Zoologico* was simply a preliminary communication; the proofs of my assertions will be given *in extenso* in a paper which will soon be published. My conclusions in that part which may interest the previous labours of Prof. Lankester may be briefly expressed as follows:—

(1) My observations have always been made on true *huitres de Marennes*.

(2) I believe that Prof. Lankester must have overlooked the recent works on the histology of Molluscs by Janssen, Rawitz and others, or he would have seen that his "gland cells" are the *becherzellen*, *cellules caliciformes* of the authors quoted; which are inside the branchial epithelium, and not on its surface, and never can be considered wandering, nor can they have amœboid movements. It would be strange, therefore, to consider such "gland cells" as similar to the amœbocytes of the blood!

(3) Prof. Lankester says that the "gland cells" contain green granules in the Marennes oysters, but this is entirely due to an optical illusion; if one examines a fresh piece of branchial lamella of the green *huitre de Marennes*, the "gland cells" appear green, but if these cells be separated from the epithelium, one finds that they are always colourless, and that they appeared green because they are surrounded with green matter. Making careful sections of the branchial lamellæ or the labial palps, one finds clearly: (*a*) that the gland cells are never green; (*b*) that the superficial epithelium is green; (*c*) that some amœbocytes and large masses included in the epithelium are also green. I am ready to furnish Prof. Lankester with microscopical preparations showing what I assert.

(4) The green of the Marennes oysters is not a hurtful substance which must be got rid of, and it is incorrect to imagine a defensive phagocytosis performed by amœbocytes. To me it is quite obvious that the green colouration is merely due to a true assimilation of nutritive substance which takes place through the agency of the epithelium in some portions of the intestine and in the branchial lamellæ. And no doubt it is the amœbocytes who carry the green substance, assimilated from the epithelium, to the liver. I am quite aware that these results of my researches are new, and it is for this reason that in communicating them to the *Monitore Zoologico* I noted that they are of some importance to our further knowledge of the physiology of mollusca.

(5) It is a mistake to believe that the oysters are green because they feed on *Navicula ostrearia*: the truth is that the alga is green for the same reason that the Marennes oysters are so, which is from the nature of the *parcs* and *claires* bottom. It is therefore the same substance, viz. the blue pigment "Marennin," which is found in both.

(6) The chemical part of my work is not concluded, and I

fear that I shall not be able to finish that most difficult task. But I may note that my assertion that "Marennin" contains principally iron, is based on the recent researches of Muntz and Chatin.
D. Carazzi.

Spezia, Italy, October 12.

Oxford Endowments.

I am surprised that my friend Dr. Hickson, whose past residence among us lends authority to his words, should so greatly misrepresent facts as to say, in Nature of October 3, that "the income of the [college] endowments is frittered away in the salaries of the heads, the stewards, the bursars, and the tutors of the pass-men," the fact being that these endowments do not provide the salaries of either the stewards or the tutors. It is further difficult to see how estates can be managed without bursars, and how bursars can exist without salaries; how complex institutions can work without heads, and how heads can live on nothing; and how the payments to bursars and heads—the latter at least with stipends fixed by statute—is in any way connected with "the [alleged] unfortunate competition that exists between colleges."
Christ Church, Oxford.
R. E. Baynes.

I am sorry that my friend Mr. Baynes should think that I have "misrepresented facts" in my article on the "Linacre Reports." I did not state, nor did I intend to imply, that the whole of the salaries of the tutors and stewards is derived from college endowments; but surely it is true that in the majority of cases these officers are fellows of their colleges, and as such receive a substantial sum of money annually from the college endowments.

I am quite competent to understand that college estates cannot be managed without bursars, and that bursars cannot live without salaries; but the estates of the Oxford colleges could be managed by less than half the number of bursars that now exist in Oxford—provided that they were chosen carefully from among those who have had some training or experience in their profession—and a large annual income would be saved from the endowments.

As to the heads. Speaking with every respect for these august persons, I still feel that with judicious amalgamation three or possibly four heads would be sufficient to carry on the official work, they now perform, with efficiency and dignity.

I should exceedingly regret if any remarks of mine should give offence to my friends in Oxford; but I never hesitated to express my opinion there or in Cambridge, that the independence of the colleges means a fearful waste of their endowments; and until, by Act of Parliament, a suitable amalgamation of these institutions is brought about, there will be little margin left for the endowment of research and the payment of those engaged in pure scholarship.
Sydney J. Hickson.

Late Leaves and Fruit.

Here, many of the roadside lindens have cast their summer foliage, and put forth a garniture of new leaves; these are fully grown, and bear the vivid tint of spring. In this city, on the 11th inst., well-grown open-air strawberries were on sale in the fruiterers' shops. The quantity altogether amounted to several bushels.
J. Lloyd Bozward.

Worcester, October 19.

THE CENTENARY FÊTES AT PARIS.

THE latter part of last week has witnessed the celebration of the first centennial anniversary of the foundation of the Institut de France. Paris was certainly not at its best, as far as meteorological features were concerned; the weather offered nothing "Queenly" or "Presidential" in its demeanour, and upon the whole was what it generally is at this time of the year—unpleasant, wet, and cold. But it hardly interfered with the proceedings and festivities, and we trust none of the generally aged guests of the Institute will be any the worse in health for their rapid visit to Paris.

A large number of foreign associates and corresponding members had promised to come; and the occasion was such a remarkable one, that we print in full the list of acceptations. Of the Académie des Inscriptions et Belles-Lettres, the Associés étrangers present were MM. Ascoli, Helbig, Max Müller, Whitley Stokes; while the Correspondants present were MM. Bailly, de Beaurepaire, Blade, Blancard, Champoireau, Chevalier, Comparetti, Delattre (le Père), De Smedt, Sir John Evans, Goeje, Gomperz, de Grandmaison, Ioret, Kern, Merlet, Millardet, Naville, Radloff, Saige, Sauvaire, Windisch. In the Académie des Sciences, the Associés étrangers who attended were Lord Kelvin and Dr. Frankland; and the Correspondants were MM. Amagat, Arloing, Backlund, de Baeyer, Bayet, Bergh, Bichat, Blondlot, Brioschi, Cannizaro, Considère, Crova, Engelmann, Sir Archibald Geikie, Gosselet, Grand Eury, Haller, Herrgott, Houzeau, Kovalewski, Laveran, Lépine, Lie (Sophus), Lockyer, Marès, Marion, Masters, Matheron, Ollier, Pagnoul, Ramsay, Raoult, Rayet, Retzius, Sir Henry Roscoe, Sabatier, Sire, Sirodot, Stephan, Sir G. Stokes, Suess, Sylvester, Général Tillo, Treub, Vallier. In the Académie des Beaux-Arts there were the Associés étrangers, MM. Alma Tadema, Da Silva, Gevaërt, Pradilla; and Correspondants, MM. Bertrand, Biot, Civiletti, Cui, Cuypers, Dauban, Deffés, De Geymuller, Gouvy, Guffens, Israëls, Lanciani, Le Breton, Loenhoff, Marionneau, Martenot, Perrin, Ronot, Salinas, Salmson, Sgambati, de Vriendt, Waterhouse, Wauters. In the Académie des Sciences Morales et Politiques, the Associés étrangers present were MM. Carlos Calvo and Castelar; and the Correspondants were MM. Aubertin, Babeau, Barkausen, Bodio, Caillemer, Ducrocq, Du Puynode, Ferrand, Lallemand, Lecky, Legrand, le Comte de Lucay, Molinari, Moynier, Sir F. Pollock, Polotsoff, Raffalovich, Stubbs, Villey Desmeserets, Worms.

At one time, it had been decided to choose the epoch of the centennial anniversary for the transfer of Pasteur's mortal remains from the vaults of Notre Dame to their final resting-place at the Pasteur Institute. The plan was not carried out, and it was better so. The frame of mind which is suitable for festivities is not so for a funeral, and it would not have been in good taste to mingle the one with the other. The plan was dismissed after short, but wise, reflection. The festivities were carried out in strict accordance with the announcements made, and published in Nature.

On the first day, the 23rd, a religious service was celebrated in Saint Germain des Près, in memory of all members of the Institute deceased since its foundation, by Monseigneur Perraud, Bishop of Autun, a member of the Académie Française, and a very distinguished writer and philosopher. It must not be thought that, even in the land of Voltaire, all men of science consider atheism as "the" proper form of philosophy. The Institute is very conservative, and whatever opinions most members may hold concerning religion and dogmas, every man has his own conception of the universe, more or less, and entertains "son petit religion à part soi," as a witty German princess put it, in her own barbarian French. This first ceremony was largely attended, although more national than international in character. The real general opening of the celebration took place the same day at 2 p.m., when the foreign associates and correspondants were received and entertained in the salon of the Institute by the members of the latter. Each *invité* was announced by the *huissiers*, and after having been introduced to the masters of the house, joined his own personal friends and acquaintances in pleasant conversation and numerous introductions to fellow-workers of every land. The masters of the house were M. Ambroise Thomas the author of *Mignon*, member of the Académie des Beaux-Arts, and for this year President of the Institute, assisted by MM. Maspero, Marey, Léon Say, Count Delaborde, delegates of the four other Academies. The last function of the day was a general reception of all members,

associates, and correspondants by the Minister of Public Instruction. The reception-rooms of the Ministry had been very elegantly adorned for the purpose. A whole series of tapestries—from the celebrated Gobelins manufactory—illustrating Don Quichotte's life, after the pictures by Coypel, decorated the walls of a large hall which had been built for the purpose, at the end of which a stage had been erected. M. Poincaré, the Minister, received most cordially his guests, who comprised, besides the members of the Institute, a large admixture of very different elements, among which political men were predominant. A very pleasant evening was provided by the singers and actors, among which were the best of the Opera and of the Théâtre Français, and by the excellent orchestra of the Opera.

On the next day (Thursday, 24th) a general meeting was held in the large hemicycle of the new Sorbonne, so splendidly decorated by the paintings of Puvis de Chavannes. The President of the French Republic was present with such Ministers as were not professionally detained at the Chambre des Députés, and after the overture of Méhul's *Joseph*—Méhul was the first composer who belonged to the Institute—three speeches were delivered. M. Ambroise Thomas began, and was short. M. Jules Simon came next, but, as his voice is weak, he could not possibly make himself heard in more than a small fraction of the hemicycle. M. Poincaré, the Minister of Public Instruction, spoke last, and very appropriately. This long ceremony ended with a fragment of *Mors et Vita*, of Gounod, played by the orchestra of the Opera.

In the morning a short reception took place at the Elysée, where the President of the Republic received the foreign members of the Institute. The foreign associates and correspondants, to the number of fifty-five, were presented to President Faure by the office-bearers of their respective Academies. The President welcomed them, and held a short conversation with each, and M. Gaston-Boissier presented him with three volumes containing the minutes of the Institute since its foundation.

In the evening a banquet took place at the Hôtel Continental; two hundred and fifty members were present. After two short "after-dinner" speeches by M. Ambroise Thomas and M. Poincaré, M. Max Müller, acting as spokesman for all the foreign members and associates, proposed the health of the Institute, "which, alone, remains unaltered and immovable in its renown and glory, while so many things have changed during this century," in very excellent terms. Most happily inspired was Lord Kelvin in his address. The very cordial and sympathetic expression which the Royal Society gave to its feelings in its address to the Institute, was received with much satisfaction, and the few words which closed the orator's speech went to the heart of all Frenchmen: "Personally, I cannot express how much I appreciate the great honour you have done me in electing me among the associates of the Institute. But I owe to France an even greater debt. She has been, truly, the *alma mater* of my scientific youth, and has inspired my admiration for the beauty of science, which during my whole life has kept me chained in her service. It was Laplace who initiated me into celestial mechanics, and a few years later the venerable Biot led me by the hand and introduced me to Regnault's laboratory. To Regnault and Liouville I shall eternally be grateful for their kindness towards me, and for the solid teaching they gave me, in 1849, on experimental physics and mathematics. M. President of the Institute, gentlemen, I thank you with all my heart. From what I have said, you will understand why I consider with perfect gratefulness France as the *alma mater* of my scientific life." Lord Kelvin spoke with his heart as well as with his reason, and the great applause which followed his speech must have told him that he had made no mistake in doing so.

The 25th was devoted to an afternoon in the Théâtre Français; the programme, to be sure, was of somewhat an austere character. The *Cid*, the *École des Femmes*, and the *Femmes Savantes* were exceedingly classical and sedate. . . . though, what might have been put in their place we could hardly decide, and classics were probably more suitable for an audience comprising a large number of foreigners than some modern play, where the *finesses* might have been a little too subtle and delicate. A very nobly-felt and worded poem by Sully Prudhomme—the most philosophical of French poets of the period—was read by Mounet-Sully, the *doyen*, the veteran of the French theatre. In the evening a reception was held at the Elysée by the President, who most graciously shook hands with the foreign members who had already been at the Elysée in the morning. The members of the Institute were all but lost in a crowd of political men, senators, deputies, officers, and functionaries who had been invited to meet them.

The last act was a visit to the magnificent residence of Chantilly, to the Duc d'Aumale. A special train left the Northern Railway Station at 11.15 a.m., carrying 239 members, and at Chantilly eleven large vehicles transported the whole assembly to the chateau, through part of the woods, the race-course, and the stables. The Duke, who had hardly recovered from an attack of gout, had to receive his guests sitting in a rolling-chair, and received them most cordially. Lord Kelvin and other members of the British contingent had some conversation with the Duke in English, and the afternoon was devoted to inspection of the residence itself, which has been splendidly enlarged and embellished by the present proprietor, and to the surrounding grounds. The whole of Chantilly and of its contents, as we have already said, has been bequeathed by the Duke to the Institute. This represents nearly £2,000,000, exactly 43,000,000 francs. As the Institute owns already some 25,000,000 francs (£1,000,000), at the death of the Duke the whole amount will be of some 70,000,000 francs (under £3,000,000). The whole Institute distributes over 725,000 francs in prizes each year.

And now the festivities are over, and most of the Institute's guests have gone back to their home or country—may their remembrances be pleasant. They have met some of their fellow-workers, and new friendships have been formed. Such meetings are profitable. While ill-feeling between nations are being daily suggested and excited by the incautious and ill-advised prose of a number of irresponsible men, it is well that occasionally the heads and lights of different countries should meet and mingle together. Knowing each other better, appreciating each other, united by a same bond to a same faith, they may, by their influence, help to further the advent of the reign of reason and goodwill. A great number of men, like Moses, have already expired in view of the Promised Land; and doubtless many more will do the same. The Promised Land seems very remote, and hardly "promised." But this is no reason for not doing what should be done, and international assemblies of the "best of the land" cannot fail to exert a useful influence.

HENRY DE VARIGNY.

This account of the *fêtes* would be incomplete if we did not give M. Jules Simon's discourse on the Institute, the delivery of which formed the central feature at the meeting in the Sorbonne. As M. Jules Simon is the foremost French orator, and his style is remarkable not only for its brilliancy but for its terseness, we give the whole oration as it was delivered.

MESSIEURS, Quand le général Bonaparte prit le commandement de l'armée d'Égypte, il signa aussitôt de la façon suivante ses proclamations et ses ordres: "Bonaparte, général en chef, membre de l'Institut." "bien sur, disait-il, d'être compris du dernier tambour."

L'Institut n'avait pas trois ans. Il a fait depuis ce temps-là quelque bruit dans le monde. Je ne puis donc me flatter d'apprendre à personne sa courte et glorieuse histoire. Je la résumerai en quelques mots pour nous réjouir en commun de ses grandeurs et non pour nous en instruire.

Les grandes assemblées qui prirent en mains le sort de la France à la fin du XVIII^e siècle eurent dès leur premier jour l'instinct révolutionnaire. Elles ne se proposèrent pas pour but de conserver les institutions existantes en les améliorant et en les purgeant de leurs abus: elles firent partout table rase, et quand elles eurent tout renversé, elles s'occupèrent, en liberté, de tout reconstruire.

Les académies avaient largement contribué à l'avènement de la Révolution. A peine eut-on passé de la théorie à l'action qu'elles trouvèrent qu'on allait trop loin. Elles avaient voulu réformer: on ne songeait plus autour d'elles qu'à détruire. La Révolution, de son côté, fit comme toutes les révolutions: elle oublia ce qu'on lui avait donné et s'irrita de ce qu'on lui refusait.

Elle se borna d'abord à des mesures malveillantes.

L'Assemblée constituante vota avec hésitation et provisoirement pour une année, en accompagnant son vote d'aigres reproches, les subventions que le Comité des Finances demandait pour les corps littéraires.[1] La Convention frappa les grands coups. Elle défendit d'abord de pourvoir aux sièges vacants, et enfin, en août 1793, elle supprima "toutes les académies et sociétés littéraires patentées par la Nation."

On a souvent remarqué que cette même révolution qui avait supprimé toutes les académies créa l'Institut, qui est une académie. Ce n'est pas versatilité dans les assemblées. La pensée de créer de toutes pièces une académie nouvelle était contemporaine de la résolution prise d'en finir avec les académies anciennes.

L'Assemblée constituante avait chargé Mirabeau de lui soumettre le plan d'une académie nationale. Mirabeau appela Chamfort qui était en querelle avec l'Académie française. Chamfort écrivit une violente diatribe et prépara un projet que Mirabeau n'eut pas le temps de lire à la tribune.

Les projets se multiplièrent sous la Convention. Condorcet, d'Alembert, Daunou, Talleyrand, tous ceux qui avaient le souci des grandes choses, apportèrent leur contribution. On dit que Talleyrand accepta la paternité d'un projet entièrement rédigé par l'abbé Desrenaudes, qu'il avait eu pour vicaire général à Autun et que nous avons connu membre du Conseil de l'Instruction publique. Talleyrand était de ceux qui peuvent se passer [illegible] taire; mais la tradition est ancienne et persistante.

Tous les auteurs de projets ont réclamé à l'envi le titre glorieux de fondateurs de l'Institut. La vérité historique exige que l'on [illegible] autre nom en tête de cette liste d'honneur, et ce nom est [illegible] de Richelieu, fondateur de l'Académie française.

Nous sommes plus justes aujourd'hui que ne l'ont été nos pères. Notre admiration pour les grandes œuvres de la Révolution ne nous cache pas les gloires de la monarchie, qui sont les gloires de la France. Nous fêtons le centenaire de l'Institut de France, mais il ne nous en coûte pas d'associer à l'honneur de cette journée le fondateur ou les fondateurs des académies dont l'Institut a reçu l'héritage, Louis XIII et Louis XIV, Richelieu, Séguier, Colbert. L'Institut existe depuis le 25 octobre 1795; [illegible] académies qui le composent remontent à 1635. Assurément l'Institut de France, depuis sa fondation, compte dans ses rangs un nombre considérable d'hommes illustres. J'en veux citer quelques-uns, avec le regret de ne pas les citer tous: Chateaubriand, Lamartine, Victor Hugo, Alfred de Musset, Alfred de Vigny, Guizot, Cousin, Thiers pour l'Académie française; Monge, Berthollet, Lagrange, Laplace, Lavoisier, Fresnel, Ampère, Arago, Cuvier, Geoffroy Saint-Hilaire, [illegible], [illegible], Claude Bernard pour l'Académie des Sciences; [illegible], Victor Le Clerc, Littré, Boissonade, Hase, Naudet, Burnouf pour l'Académie des Inscriptions; Louis David, Ingres, [illegible], Meissonier, David (d'Angers) pour l'Académie des Beaux-Arts.

J'avais arrêté là cette liste de nos gloires contemporaines pour obéir à la loi qui m'est imposée de ne prononcer le nom d'aucun vivant: faut-il que je doive aujourd'hui ajouter le nom d'un homme que j'ai connu il y a plus de cinquante ans, à l'École normale où il était élève, où j'étais professeur, qui était notre ami à tous, car on ne pouvait le connaître sans l'aimer, et qui était avant tout l'ami et le bienfaiteur de l'humanité: le nom immortel de Louis Pasteur? Les voûtes de cette salle gardent l'écho des acclamations qui l'accueillirent quand il vint, à cette place même, recevoir les hommages du monde savant. L'humanité, ce jour là, fut reconnaissante et juste.

Ainsi l'Institut de France a eu, dès son premier siècle, une magnifique floraison de grands hommes. Nous sommes fiers de nos gloires nouvelles: mais nous gardons pour nos gloires séculaires un culte reconnaissant et filial. Nous ne renonçons ni à Corneille et Racine, ni à Boileau, ni à La Fontaine, ni à Bossuet, ni à Voltaire, ni à Montesquieu, ni à Buffon, ni à Clairaut, ni à d'Alembert, ni à Huyghens, ni à Mariotte, ni à Mabillon, ni à Rollin, ni à Turgot, ni à Lebrun, ni à Mignard, ni à Lesueur, ni à Philippe de Champagne, ni à Mansart, ni à Soufflot.

Messieurs, le drapeau aux trois couleurs est toujours pour nous "le drapeau chéri"; c'est l'astre de la liberté et de la civilisation; mais nous suivons avec amour et orgueil le drapeau blanc fleurdelisé remontant les âges jusqu'au siècle qui fut le grand siècle et qui reste par excellence le siècle français.

C'est le 29 janvier 1635 que l'Académie française reçut sa consécration officielle. L'Académie des Beaux-Arts eut le même honneur en 1648, l'Académie des Inscriptions en 1663 et l'Académie des Sciences en 1666.

Il ne suffit pas d'avoir restitué la création des académies à Louis XIII et à Richelieu, il faut remonter jusqu'à Conrart. La première en date, l'Académie française, est, comme beaucoup de grandes choses, due à l'initiative privée. Conrart n'était rien. Il n'est rien devenu. Il n'est célèbre que par son silence: un genre de célébrité créé tout exprès pour lui par Boileau. C'est lui qui eut l'idée de donner un règlement à une compagnie qui se réunissait tour à tour chez chacun de ses membres pour parler de littérature. Ils étaient neuf en le comptant. De petits hommes, dit Voltaire, d'un ton dédaigneux. Des hommes obscurs, dit-il ensuite en parlant des premiers académiciens au nombre de vingt-huit qui reçurent ce titre après les lettres royales de 1635. Sans doute on n'eut pas sur-le-champ un Corneille ou un Racine à introduire dans l'Académie. Il fallut attendre douze ans pour Corneille, trente-six ans pour Bossuet, trente-sept ans pour Racine, quarante-neuf ans pour La Fontaine et Boileau. L'assemblée se garnissait de grands hommes peu à peu. Elle ne devait jamais avoir quarante grands hommes. Aucune assemblée en aucun temps et chez aucun peuple ne pourra en avoir à la fois qu'un nombre très limité. Ceux que Voltaire appelle de petits hommes ne sont peut-être pas aussi petits qu'il le croit. Ils semblent petits à la postérité; ils étaient grands pour leurs contemporains. Apprenons, ne fût-ce que par prudence, à respecter les hommes d'élite qui ne sont ni des Voltaire ni des Molière. On ne peut pas, et on ne doit pas se tromper sur les hommes de génie; on peut hésiter sur le choix entre les hommes vraiment supérieurs sans être grands, ceux que j'appellerai les hommes distingués dans le genre médiocre.

C'est un honneur pour la société éclairée du XVII siècle d'avoir su le-champ attaché de l'importance à cette réunion de quelques hommes de goût, qui ne s'occupaient entre eux ni de religion ni de politique, et parlaient uniquement des lettres et des ouvrages de l'esprit. L'amour des lettres est resté un des caractères de notre génie national. Dès que le public fut admis aux réceptions de l'Académie française, il y courut. Quand elle ouvrit en 1702 ses portes aux femmes pour ces jours-là, les femmes affluèrent. L'Académie n'a eu garde de renoncer à cet usage qui a pris avec le temps plus de solennité. Une réception à l'Académie est, par excellence, un événement parisien. Il faut y avoir assisté; il faut avoir son avis sur les deux discours. On attache moins d'importance aux séances les plus passionnantes de la Chambre. La fameuse coupole est un instrument de torture; on y étouffe, on y perd connaissance. Ces femmes évanouies sont un accroissement de succès pour les deux orateurs. Elles font penser aux corridas espagnoles, qui ne sont admirables, au dire de leurs ennemis, que quand un toréador a été tué.

On parla de la société de Conrart au cardinal de Richelieu. Il avait l'instinct du grand et du stable. Il jugea que cette compagnie pouvait devenir une institution. Il offrit aux amis

[1] [illegible] l'Académie française, [illegible] livres, plus 1,200 livres pour un prix à [illegible] pour l'Académie des Belles-Lettres, [illegible] livres; pour l'Académie des [illegible], [illegible] livres; ces deux Académies devaient aussi décerner [illegible] de [illegible] livres.

de Conrart de reconnaître officiellement l'existence de leur association. Ce fut à peu près tout ce qu'il offrit; "des privilèges honorables, dit Voltaire, aucun d'utile, son fondateur ne lui ayant même pas procuré une salle d'assemblée."

En réalité, il ne rendait à l'Académie d'autre service que de ne pas l'ignorer, mais il pensa, et tout le monde pensa avec lui, que puisqu'il ne l'ignorait pas, il la gouvernait. Plusieurs des amis de Conrart hésitèrent. Ce qu'ils avaient cherché, c'était la liberté, on leur offrait l'assujettissement. Cette résistance ne pouvait durer; on ne résistait pas au roi, ni au cardinal, qui était le roi. Refuser une grâce qu'ils offraient, c'était plus que résister, c'était désobéir. On céda, on remercia. On exalta le roi et le grand ministre Richelieu qui promettait de protéger.

Il y eut une autre difficulté à la création officielle de l'Académie. Le Parlement aussi eut la velléité de résister. On sait que l'enregistrement était alors nécessaire pour donner efficacité aux décisions royales. Le Parlement pouvait retarder, il pouvait faire des observations et même des remontrances. A la fin, dans les grandes occasions, on avait raison de lui par un lit de justice. On n'alla pas jusqu'à ces extrémités pour la transformation des réunions de Conrart en Académie royale; mais le Parlement manifesta sa mauvaise humeur par un retard d'un an. Le cardinal fut obligé de faire entendre qu'il voulait être obéi.

On a cherché la cause de cette mauvaise volonté du Parlement. Il ne s'agissait pas de la création d'une cour souveraine, mais "de simples peseurs de syllabes et de jurés fabricateurs de mots," comme disaient les mauvais plaisants de l'époque.

Le Parlement, suivant Voltaire, craignit que l'Académie ne s'attribuât quelque juridiction sur la librairie, et ajouta cette clause aux lettres patentes du roi: "L'Académie ne connaîtra que de la langue française et des livres qu'elle aura faits ou qu'on exposera à son jugement."

Je crois plutôt que le Parlement craignait pour l'autorité qu'il s'attribuait en matière religieuse et philosophique. La question des académies touchait à la question des écoles. La théologie était tout près; plus l'autorité du Parlement était contestée en matière religieuse, plus il s'en montrait jaloux. Il obéissait dans toute cette affaire au même esprit qui inspira plus tard la réforme de l'Université par le président Rolland.

Le roi, et je parle ici de Louis XV autant que de Louis XIV et de Louis XIII, fut constamment pour les académies un bon maître, mais un maître. Les élections durent être soumises a son approbation; c'est un droit qui a toujours été conservé au pouvoir public; il existe encore aujourd'hui. Louis XIV l'exerça une fois dans une occasion très éclatante. Il voulait l'élection de Boileau; l'Académie élut La Fontaine. Le roi refusa son approbation. L'Académie s'empressa d'élire Boileau à la première vacance. "A présent, dit le roi, vous pouvez procéder à la réception de La Fontaine."

Le roi intervint aussi, mais bien rarement, dans les travaux de l'Académie. C'est lui, ou plutôt c'est Richelieu, auteur de la tragédie de *Mirame*, qui prescrivit cet examen du *Cid* inventé pour exalter la gloire du cardinal et dont le résultat fut de montrer dans tout son éclat la gloire de Corneille. Voltaire, au siècle suivant, sous prétexte d'impartialité et en mêlant l'apothéose à la critique, essaya la même entreprise et aboutit au même résultat.

Les académiciens, un moment détournés de leurs travaux plus paisibles, revinrent au Dictionnaire. On ne manqua pas sous la Révolution de leur reprocher de n'avoir fait ni la Grammaire, ni la Poétique que le roi attendait d'eux et d'avoir mené trop lentement le travail du Dictionnaire.

L'Académie n'était pas si coupable qu'on le croyait. Des trois objets confiés a ses soins, elle avait choisi le Dictionnaire, qui rendait à la langue le double service d'en fixer les termes et d'en expliquer les règles par des exemples empruntés aux meilleurs écrivains.

Le Dictionnaire avançait lentement. Cette lenteur fait sa force. Les variantes qu'il enregistre ont toutes été jugées et consacrées par le temps, avant de recevoir cette confirmation officielle.

Le Dictionnaire est à lui seul toute l'Académie française. A notre langue essentiellement souple et vivante, qui exprime avec facilité les passions et les idées à mesure qu'elles se renouvellent et qui suffit, sans néologismes, à l'exposition et à la démonstration des découvertes scientifiques, il donne la solidité et la majesté des deux langues qui ont successivement incarné la Grèce et Rome.

Louis XIV voulait qu'il y eût une langue de Louis XIV comme il y avait une langue de Périclès et une langue d'Auguste, et il revendiquait pour lui-même l'honneur de cette pensée lorsqu'il disait: "Le soin des Lettres et des Beaux-Arts ayant toujours contribué à la splendeur des États, le feu roi, notre très honoré seigneur et père, ordonna en 1635 l'établissement de l'Académie française pour porter la langue, l'éloquence et la poésie au point de perfection où elles sont enfin parvenues sous notre règne."

Je n'ai garde d'insister; je dis la pensée de Louis XIV et de ceux qu'on appelait dès lors les Quarante.

Notre admiration pour nos chefs-d'œuvre et notre langue ne nous empêche pas d'admirer la gloire des autres nations. Nous nous sommes associés au centenarie de Shakespeare; Gœthe, Schiller, Cervantès sont populaires dans nos écoles. Nul n'entrera jamais sans une respectueuse et solennelle émotion dans cette église de Santa-Croce à Florence où sont réunis, autour du cénotaphe du Dante, les tombeaux de Galilée, de Michel-Ange, de Machiavel, d'Alfieri, de Cherubini.

Le XVIII siècle reprochait toujours aux académies et surtout à l'Académie française, qui portait le poids des querelles parce qu'elle avait porté celui de la gloire et parce que le public pouvait plus facilement suivre ses travaux, d'avoir élu des hommes médiocres et d'avoir laissé en dehors d'elle des hommes de génie.

Je connais deux hommes de génie qui n'ont pas été de l'Académie française, Descartes et Molière. Rousseau, dont on prononce quelquefois le nom à propos des omissions de l'Académie, était citoyen de Genève.

Deux erreurs en un siècle et demi! Les hommes se trompent ordinairement plus que cela. La plupart des ouvrages de Descartes sont écrits en latin. Le *Discours de la Méthode*, qui est un des grands monuments de la langue française, n'était connu que d'un petit nombre de savants et de philosophe. Le grand éclat de la renommée de Descartes n'a commencé qu'après sa mort, quand on a enfin compris qu'il avait émancipé la raison humaine. Molière avait contre lui sa profession; on se rirait aujourd'hui, avec raison, d'un tel obstacle. C'était quelque chose sous Louis XIV. Messieurs les tapissiers valets de chambre du roi n'auraient plus voulu être de l'Académie. Je ne sais pas ce que Molière lui-même aurait pensé de son élection. On était alors conservateurs du rang comme on l'est aujourd'hui de la propriété. Il fallut contraindre Catinat à se laisser faire maréchal de France.

Quant aux autres grands hommes dont la Convention regrettait si amèrement l'absence, ils apartenaient à la catégorie de ceux que nous appelions tout à l'heure des hommes distingués dans le genre médiocre. Ils étaient admirés, à juste titre, par leurs contemporains; la postérité a le droit de choisir entre eux. Dufresny, Raynal, Helvétius sont des grands hommes dont on blâmait en 1793 l'omission, et dont on blâmerait aujourd'hui l'élection si l'Académie les avait élus.

De tous les griefs dirigés contre l'Académie, le plus fréquemment invoqué était sa courtisanerie envers le roi. C'était une compagnie de courtisans qui pouvait, en ce genre, donner des leçons à tous les Dangeau. N'est-ce pas elle qui avait mis au concours cette question: "Quelle est celle des vertus du roi qui mérite le plus d'être louée?"

On était bien loin de ce style et de ces sentiments lorsque Grégoire, reprochant au "bon Fénelon" d'avoir fait un traité sur la direction de la conscience d'un roi, ajoutait: "Comme si les rois avaient de la conscience! Autant eût valu disserter sur la douceur des bêtes fauves."

Le tort des hommes aveuglés par la passion est de vouloir toujours juger sans tenir compte des temps et des milieux. N'en déplaise aux niveleurs de 1793, l'esprit libéral qui s'était manifeste dans le sein de l'Académie au moment de sa création officielle subsista pendant toute sa durée. Il s'associait chez elle à une admiration pour le roi dont nous ne comprenons plus la nature. L'Académie voyait la France dans le roi. A cette époque de l'histoire, on n'était puissant qu'à condition d'être dépendant. Ce qui est indiscutable, c'est que les académies entourées d'honneurs par la monarchie étaient devenues peu à peu de véritables aristocraties. Elles avaient aux yeux des republicains le double défaut d'être des corporations, et des corporations privilèges, très entichées de leurs privilèges. Un usage introduit par Colbert, ou plutôt par l'abbé Bignon, son neveu et son représentant dans le gouvernement des sociétés savantes, divisait les Académies des Inscriptions, des Sciences et des Lettres en trois classes d'académiciens: les honoraires, les pensionnaires et les élèves; ce qui constituait un privilège

dans le privilège. Seule l'Académie française avait énergiquement refusé de subir l'affront de ce règlement.

L'Académie française avait toujours eu dans son sein, depuis sa création, des ducs, des maréchaux, des évêques, des magistrats de cours souveraines. Ces grands seigneurs apprenaient à traiter les gens de lettres comme des égaux ; mais, en même temps, les gens de lettres apprenaient à se croire grands seigneurs. Ils se donnaient des compliments les uns aux autres, pour s'exercer à leur fonction principale qui était d'encenser le roi et le ministre. Les compliments sont devenus nos discours de réception : Voltaire n'était pas tendre pour eux : "Ce que j'entrevois dans ces beaux discours, dit-il, c'est que le récipiendaire ayant assuré que son prédécesseur était un très grand homme, que le cardinal de Richelieu était un très grand homme, le chancelier Seguier un assez grand homme, le directeur lui répond la même chose, et ajoute que le récipiendaire pourrait bien aussi être une espèce de grand homme, et que pour lui, directeur, il n'en quitte pas sa part" ; et plus loin : "La nécessité de parler, l'embarras de n'avoir rien à dire et l'envie d'avoir de l'esprit sont trois choses capables de rendre ridicule même le plus grand homme."

La Convention pouvait-elle souffrir l'existence d'un corps qui passait son temps à célébrer les vertus des rois, qui était lui-même un corps privilégié, et qui comptait dans son sein des membres investis d'un double privilège? C'était l'aristocratie de l'esprit, mais c'était une aristocratie. La Montagne et la Plaine étaient d'accord pour la renverser.

Il s'était pourtant passé vers le milieu du XVIII^e siècle un fait considérable qui aurait pu modifier les jugements des révolutionnaires. Voltaire était entré à l'Académie. Les académiciens s'étaient vaillamment défendus. Voltaire fut refusé deux fois. Enfin, il entra ; et dès ce jour l'Académie lui appartint. Il avait déjà son journal qui était l'*Encyclopédie*. L'*Encyclopédie* entra avec lui à l'Académie, qui fut ainsi transformée par anticipation en véritable Académie des Sciences morales et politiques. Il y fit nommer successivement Duclos, d'Alembert, Marmontel, Condillac, Morellet. Il échoua pour Diderot. Il s'en plaint vivement, et avec raison du reste, car si Diderot n'est pas précisément un génie académique, c'est sans conteste un homme supérieur. Voltaire écrit à l'abbé d'Olivet : "Tâchez, mon cher maître, de nous donner un véritable académicien à la place de l'abbé de Saint Cyr et un savant à la place de l'abbé Salier. Pourquoi n'aurions-nous pas cette fois-ci M. Diderot? Vous savez qu'il ne faut pas que l'Académie soit un séminaire et qu'elle ne doit pas être la Cour des pairs. Quelques ornements d'or à notre lyre sont convenables ; mais il faut que les cordes soient à boyau et qu'elles soient sonores."

Voltaire n'était pas accoutumé aux échecs et avait pris sa revanche. Il avait le gros de son armée à l'Académie française, il avait à l'Académie des Sciences Condorcet, d'Alembert, Fontenelle. L'Académie des Inscriptions était plus résistante, mais il avait pénétré partout. Il était l'oracle des cercles de précieuses dont l'influence avait remplacé l'influence décroissante de la cour. Mme. de Lambert, Mme. de Tencin, Mme. Du Deffand, Mlle. de Lespinasse, Mme. Geoffrin, Mme. Du Chatelet recevaient ses inspirations. Il était l'ami (intermittent) du roi de Prusse, le correspondant (et le flatteur) de la grande Catherine. Il avait traité Corneille de haut : il se croyait plus pathétique que Racine. En philosophie il tenait tête au clergé, tout en faisant ses pâques à Ferney et en dédiant au pape sa tragédie de *Mahomet*. Quand on le juge à présent, on ne peut s'empêcher de voir en lui un précurseur de la Révolution. Voltaire et toute l'armée qu'il commandait avaient, en effet, semé les idées révolutionnaires, mais ils avaient cru évoquer un génie ; et quand ils furent en face de lui (je parle des lieutenants de Voltaire, car il était mort en 1778), il leur sembla qu'ils avaient évoqué le diable.

Ils s'arrêtèrent en chemin, et devinrent, par cela même, les plus grands ennemis de leurs anciens amis. On pourrait ici parodier cette grande parole : "Il y a plus de joie dans le ciel pour un pécheur qui se repent. . . ." et dire : "Il y a plus de [illegible] dans l'armée révolutionnaire pour un ami qui s'arrête en chemin . . ."

Les [illegible], dont on oublia les services, eurent le sort des parlements et du clergé. Grégoire, dans un rapport ridiculement emphatique, proposa la suppression des académies, tout en demandant que "au milieu des décombres, le sanctuaire des arts, [illegible] le temple de la liberté, présentât la réunion organisée de tous les savants et de tous les moyens de science."

"[illegible], disait-il, la République française fera son entrée dans l'univers. En ce jour où le soleil n'éclairera qu'un peuple de frères, les regards ne doivent plus rencontrer sur le sol français d'institutions qui dérogent aux principes éternels que nous avons consacrés, et cependant quelques-unes, qui portent encore l'empreinte du despotisme ou dont l'organisation heurte l'égalité, avaient échappé à la règle générale : ce sont les académies."

Deux ans après avoir congédié les académies avec cette politesse, la Convention faisait une grande, une très grande chose. Elle les rétablissait, et en les rétablissant, elle leur faisait subir une modification profonde. Le rêve d'une assemblée unique des savants et des artistes, des poètes et des philosophes, déjà conçu par la Constituante, devenait une réalité. Jamais la fraternité des lettres, des sciences et des arts n'avait été affirmé avec cet éclat. La nouvelle institution réunissait en un faisceau toutes les forces de la passion et de la pensée. Elle créait au-dessus de la société vulgaire, occupée des soins de la vie, une sorte de monde à part d'où sortiraient sans cesse pour éclairer l'humanité, pour la fortifier et la charmer, des vérités et des chefs-d'œuvre. L'Institut ne participerait pas au gouvernement, il ne serait pas chargé de l'enseignement. Son action serait d'une nature plus haute ; elle s'exercerait par l'exemple. De même que le Dieu d'Aristote meut sans être mû et peut ignorer le monde auquel il donne la vie, il suffit aux savants et aux poètes d'être, et d'être connus. Leurs œuvres produisent le mouvement, et en même temps elles le règlent par l'admiration qu'elles inspirent.

Daunou parlant au nom de la Convention disait : "Nous avons emprunté de Talleyrand et de Condorcet le plan d'un Institut national, idée grande et majestueuse dont l'exécution doit effacer en splendeur toutes les académies des rois. . . . Ce sera en quelque sorte l'abrégé du monde savant, le corps représentatif de la république des lettres, un temple national dont les portes toujours fermées à l'intrigue ne s'ouvriront qu'au bruit d'un juste renommée."

Cette union majestueuse et féconde de tout ce qu'il y a d'éternel dans le sentiment et la pensée n'est pas la seule grandeur de l'institution nouvelle. Les académies jusque-là avaient été purement locales. Elles se recrutaient dans une seule ville et représentaient le mouvement scientifique ou littéraire de la ville où elles étaient nées. Mais l'Institut créé en 1795 pour remplacer les académies n'est pas un institut parisien, c'est un institut national, c'est l'Institut de France. La constitution de l'an III, dont la formule est fidèlement reproduite par la constitution de l'an VIII, le déclare en ces termes solennels : "Il y a pour toute la République un Institut national chargé de recueillir les découvertes, de perfectionner les arts et les sciences."

Pourrais-je oublier, en présence de cette assemblée, que la Convention nationale ouvrit les portes de son Institut non seulement à tous les Français, mais à tous les grands hommes quelle que fût leur origine? De même que Louis XIV récompensait le génie à quelque nation qu'il appartînt, la Convention créa dans le sein de l'Institut l'ordre des associés étrangers, qui nous permet d'inscrire sur nos listes d'honneur Huyghens, Newton, Leibniz, et plus près de nous Rossini et Meyerbeer.

L'œuvre de la Convention n'est donc pas la reproduction des anciennes académies déguisées sous des noms nouveaux et modifiées dans les détails secondaires de leur organisation. C'est bien une œuvre nouvelle. C'est une création, une puissante création. C'est l'Académie de France, représentant à la fois les lettres, les sciences et les arts. Elle contient les anciennes académies, mais en les enfermant dans une synthèse nouvelle et forte. C'est notre droit et notre devoir, en ce jour de fête, d'adresser également nos hommages aux anciennes académies qui ont préparé l'Institut et à l'Institut qui contient et complète les anciennes académies.

L'œuvre de la Convention est assez belle pour que nous puissions avouer maintenant que l'Assemblée avait été moins heureuse dans les détails d'exécution que dans la conception première. Elle avait tout exagéré : sa propre autorité sur l'Institut et l'autorité de l'Institut sur les membres qui le composaient. Elle ne connaissait pas la liberté. Elle disait comme Louis XIV : "L'État, c'est moi," et quand elle avait usurpé tous les pouvoirs, elle disait : "Nous voilà libres."

La première faute de la Convention, en ceci comme en bien d'autres choses, fut son amour immodéré de la table rase. Elle avait supprimé les académies qu'elle pouvait modifier en les conservant. Elle supprima jusqu'à leurs noms dans la réorganisation qu'elle fit ensuite. On a dit d'elle avec vérité qu'elle avait

peur des mots. Elle remplaça ces noms illustres par les appellations vulgaires de première, seconde, troisième classe, et ne réussit par ces changements qu'à voiler les traditions historiques. Elle effaça un autre nom qui aurait dû lui être particulièrement sacré. Ayant à placer la philosophie dans la classe des sciences morales et politiques qu'elle organisait pour la première fois, elle remplaça ce nom, qui pouvait rappeler les croyances spiritualistes, par celui d'Analyse des sensations et des idées, qui ne rappelait que Condillac. Chaptal, qui déjà en 1801 reprochait à l'organisation de l'Institut "de s'être beaucoup trop écartée de ce que l'expérience avait montré de perfection dans la composition de nos anciennes académies," fit en 1803 un nouveau projet où il se montra plus équitable et plus habile que la Convention. Il proposait même de rétablir le nom des anciennes académies, dont la France s'honorait depuis plus d'un siècle, et qui étaient devenues le modèle des institutions savantes et littéraires formées successivement dans tous les Etats de l'Europe. Le Conseil d'Etat ne voulut pas y consentir. Il approuva le fond de la proposition, mais il ne rendit pas leurs noms aux anciennes compagnies.

L'Académie des Sciences morales et politiques, fondée pour la première fois en 1795, et qui formait la seconde de l'Institut, eut une courte existence. Le Premier Consul avait dit un jour à M de Ségur : "Vous présidez la seconde classe de l'Institut ; je vous ordonne de lui dire que je ne veux pas qu'on parle de politique dans les séances. Si la classe désobéit, je la casserai comme un mauvais club." Fidèle jusqu'au bout à son aversion pour ceux qu'il appelait les idéologues, quand il procéda à la réorganisation de l'Institut en 1803, il supprima la deuxième classe par prétérition, en supprimant son nom et en répartissant ses membres dans les autres classes.

La première faute de la Convention fut donc de renoncer à des noms vénérables et à un passé illustre ; elle fit une seconde faut dans le mode d'élection qu'elle adopta. Les candidats furent présentés par la classe dans laquelle s'ouvrait une vacance, et l'Institut en corps fut chargé de choisir entre les candidats ainsi présentés. Jamais la compétence ne fut traitée avec un pareil mépris. Un comédien décidait de l'élection d'un mathématicien. Un peintre jugeait un philosophe. On reconnaît bien là une assemblée qui admettait les juifs au nombre des votants pour l'élection des évêques catholiques. L'élection par classe ou académie ne fut établie qu'en l'an XI, sur le rapport de Chaptal.

La Convention commit une troisième faute. Les deux premières avaient pour effet d'exagérer l'unité ; celle-ci exagérait et faussait le caractère national de l'Institut. C'était l'Institut de France ; on voulut qu'à ce titre il fût composé par moitié de Parisiens et de provinciaux. Il aurait suffi de dire que les choix pouvaient se porter également sur les hommes du premier mérite, qu'ils eussent leur résidence à Paris ou ailleurs. Non. Il sembla plus radical de partager par moitié. Cela cessait même d'être juste, car Paris ne comptait que 500,000 habitants et la province en avait 25 millions. Et cela n'était pas raisonnable : car un homme d'élite peut désirer le séjour de Paris à cause des bibliothèques, des musées, des amphithéâtres et de tous les autres moyens d'étude. On avait admis une section de l'art dramatique : trois comédiens parisiens, trois comédiens de province. Tout le monde sait que les grands comédiens peuvent se former en province, mais qu'ils ne peuvent y rester. Ils n'y trouvent ni les traditions, ni les écoles, ni les auxiliaires, ni le public dont ils ont besoin, ni les ressources materielles. On en peut dire autant des érudits, des artistes. La regle de résidence était sévère alors ; plus sévère qu'elle ne l'a été depuis. Un membre nommé pour représenter Paris et qui s'établissait définitivement en province était obligé de donner sa démission. Destutt de Tracy, qui habitait Auteuil, fut nommé membre non résident.

La plus grande erreur commise est peut-etre le règlement intérieur des travaux imposé par décret organique.

Le gouvernement s'attribuait dans ce règlement le droit de requérir l'avis des classes de l'Institut. C'est surtout à l'Academie des Sciences qu'il adressa ses réquisitions. Il la consulta sur les voitures couvertes destinées au transport des malades, sur le perfectionnement à apporter au régime des hopitaux, sur le système monétaire, sur la manière d'accorder l'ere de la République avec l'ère vulgaire, sur un nouveau boulet, sur un taffetas huilé propre à faire des manteaux pour les troupes, sur l'idée de fair établir plusieurs rangées de canons sur un seul affût, sur la conservation des eaux potables à bord des navires, sur la nservation des biscuits et des légumes en mer. Il y avait aussi des questions pour les autres classes, meme des questions philosophiques, ce qui tendait à faire une doctrine d'État. Rien n'est plus contraire à la philosophie et à la vraie politique, et rien ne peut nuire davantage aux progrès de la science et à l'éclat des académies. Dans un corps littéraire bien organisé, l'autorité de chaque membre s'accroît de celle de la compagnie, mais a condition qu'il n'en résulte aucune ingérence de l'académie ni des gouvernements sur le travail individuel. Quand le général Cavaignac, pour réfuter les socialistes de 1848, demanda a l'Académie des Sciences morales et politiques des petits livres populaires, l'Académie échoua, il faut le dire résolument, quoiqu'elle se fût adressée aux plus grands noms de la science. Un grand esprit ne se retrouve pas dans un travail fait sur commande : il faut au génie l'air de la liberté.

Ce droit de réquisition n'était pas seulement attribué au gouvernement, il appartenait aussi au public. Tout auteur pouvait exiger une analyse de son livre, tout inventeur un examen de sa découverte. Ainsi les académiciens n'étaient plus maitres de leur temps. Je ne m'étonne plus qu'on leur eût attribué deux costumes : un costume de cérémonie et un costume de travail. On ne voyait pas qu'assujettis au service de tout le monde, il ne leur restait plus de temps pour le service de la science.

Je ne veux pas tout énumérer. Je citerai pourtant la suppression des secrétaires perpétuels, remplacés par deux secrétaires semestriels : c'était ôter aux académies leur unité, leur vie. Chaptal, en 1801, parlant des anciennes académies, disait : "Le même homme suivait tous les details de l'Académie, en devenait l'historien, et attachait d'une manière toute particulière la gloire de son nom à celle du corps dont il etait l'organe ; il y avait plus de suite dans l'administration, plus de célérité dans l'exécution, plus d'ordre dans la marche, et on ne peut pas nier que le rétablissement d'un secrétaire perpétuel pour chaque classe de l'Institut, en rouvrant une carrière qui présente tant de grands hommes pour modeles, ne contribuât à la gloire de ce corps et aux progres des sciences." Et plus tard, en 1803, il revenait à la charge - "Le rétablissement de ces places, disait-il en parlant des secrétaires perpétuels, fera renaître une branche d'éloquence très négligée depuis dix ans et donnera aux travaux académiques cet esprit de suite, cet enchaînement de faits et de pensées qui, seuls, peuvent fixer l'époque des découvertes et tracer avec exactitude l'histoire des connaissances humaines."

Tout en déclarant qu'elle renonçait au passé académique, la Convention, par la force meme des choses, avait conservé à son Institut tous les avantages dont avaient joui les anciennes académies. Elle maintenait, la reconnaissance de l'Institut par l'État et l'intervention de l'État dans les règlements intérieurs de l'Institut. Elle laissait à l'Institut le local des academies, la bibliothèque, la participation à la nomination des professeurs dans les grands établissements littéraires et scientifiques. L'Institut a conservé cette prérogative et présente encore aujourd'hui des candidats pour le Collège de France, le Muséum, l'Académie, de Rome, les Écoles de Rome et d'Athènes, l'École des Chartes, l'École des Langues orientales vivantes, le Conservatoire des Arts et Métiers, l'Observatoire, l'École Polytechnique. Il a conservé les impressions gratuites et les prix connus sous le nom de prix du budget, auxquels s'ajoutent à présent des prix fondés par l'initiative privée, dont le chiffre annuel n'est pas inférieur à 524,500 francs. Le 29 messidor an IV la Convention donnait aux membres de l'Institut une indemnité annuelle de 750 myriagrammes de froment, et le 19 thermidor suivant, elle décidait que "sur cette indemnité, il serait distrait a l'égard de chacun des membres une somme egale à la valeur de 150 myriagrammes de froment, pour être répartie par forme de droit de présence entre les assistants aux séances, tant générales que particulieres, de chaque classe."

En 1803, sur le rapport de Chaptal, on permit aux membres de l'Institut d'être de plusieurs académies à la fois, et par conséquent de réunir plusieurs indemnités. "C'est, dit Chaptal, le moyen d'ouvrir aux hommes distingués plusieurs routes à la gloire et à l'aisance, et par conséquent le moyen de multiplier et d'agrandir les talents."

Le droit de cumuler les académies subsiste, mais on a enlevé celui de cumuler les indemnités. Nous en sommes restés aux 750 myriagrammes. Ceux d'entre nous qui font partie de plusieurs académies ne touchent l'indemnité qu'une seule fois. Nous nous vantons de n'être pas riches.

Les membres de l'Institut, quand on fixait à 750 myriagrammes de froment, c'est-à-dire, pour parler en langage intelligible, à 1500 francs, l'indemnité qui devait les delivrer de

… les soucis de la vie, n'imaginaient pas dans leurs rêves les plus ambitieux qu'ils auraient un jour à eux l'un des plus beaux palais du monde, avec une galerie de tableaux, une bibliothèque créée d'une seule venue par un grand écrivain doublé d'un érudit consommé, des bois, des eaux, et tout un monde de beaux souvenirs.

Peut-être est-il bon de rappeler ici, pour expliquer à la fois notre richesse et notre pauvreté, que tous les dons faits à l'Institut sont faits à la science ou aux pauvres. Les membres de l'Institut n'en profitent jamais. Une nouvelle donation n'est pour eux qu'un surcroît de travail. L'empereur Napoléon III voulut un jour élever à 5000 francs l'indemnité annuelle de 1500 francs, ce qui faisait une quantité froment fort respectable. L'Institut, consulté, exprima sa reconnaissance, et refusa.

On a dit quelquefois que tous les efforts de la Révolution pour transformer les académies n'avaient été qu'une illusion. Le 8 août 1793, on les supprime; le 25 octobre 1795, on les remplace par l'Institut. On s'aperçoit sur-le-champ que cet Institut, à force d'être nouveau, n'est pas viable. Dès 1803 on commence à le réformer; les réformes se multiplient d'année en année, et à quoi aboutissent-elles? à supprimer la plupart des innovations, à refaire les anciennes académies et même, en 1816, à leur rendre leur nom.

Ceux qui parlent ainsi ne voient pas qu'il reste à la Révolution la gloire d'avoir établi un lien étroit entre les académies, d'avoir compris la solidarité des lettres, des sciences et des arts, d'avoir mis les académies en communication plus intime avec le public et de leur avoir donné de nouveaux et sérieux moyens d'influence.

Des anciennes compagnies, des remaniements opérés sur les nouvelles est résulté l'Institut actuel, où la protection de l'État n'exclut pas la liberté des membres, où chacun répond seul de sa doctrine, où la solidarité d'honneur qui unit tous les membres rend impossibles les excentricités, où tous les travaux tendent à la manifestation de la vérité et aux triomphes de l'art, où tous les membres rassemblés sans être confondus se prêtent une mutuelle assistance sans jamais tomber dans la confusion: un corps enfin qui réunit dans une juste proportion l'autorité et la liberté, et qui mérite d'être proposé comme modèle à toutes les nations civilisées.

J'ose ajouter, Messieurs, que votre présence ici, celle du chef respecté de l'État, et l'éclat qui en résulte vont donner à l'Institut national de France une consécration nouvelle.

Le monde assiste depuis vingt-cinq ans à un singulier spectacle. D'une part les gouvernements multiplient avec une sorte de rage les préparatifs de guerre. Ils construisent des forteresses, ils coulent des canons, ils emplissent les arsenaux de projectiles; ils imposent le service militaire dans l'armée active à tous les jeunes gens sans exception, au point de vider les écoles, de désorganiser les services publics et particuliers, d'ôter à l'agriculture et à l'industrie les bras dont elles ont besoin. Ils retiennent les citoyens dans les liens du service militaire jusqu'à quarante-cinq ans. Il semble que la bataille doive se livrer demain.

En même temps tous les philosophes, tous les publicistes, les hommes d'État, les souverains eux-mêmes protestent à grands cris de leur horreur pour la guerre. Ils veulent la paix, il la leur faut pour rendre au travail la sécurité, à l'intelligence ses droits et à l'année son printemps. On fonde de toutes parts des ligues pour la paix, on assemble des congrès pour protester contre la paix armée, plus ruineuse et plus meurtrière que la guerre.

Hélas! ces congrès n'apportent que des vœux. C'est beaucoup et ce n'est rien. Ils apportent des vœux, je n'ose pas dire qu'ils apportent des espérances.

Ce qu'il faut à l'humanité, ce ne sont pas des paroles, ce ne sont pas des soupirs, ce sont des actes. Ce qui fera renaître la fraternité entre les hommes, ce sont grands travaux faits en commun, de grand services rendus à l'humanité.

Le voilà devant vos yeux, le congrès de la paix! Voilà le congrès où la vérité est aimée pour elle-même, quel que soit le pays où elle éclate, où la poésie est adorée dans toutes les langues, où les grandes découvertes excitent le même enthousiasme, quelle que soit leur origine, et où l'on ne connaît d'autre émulation que celle de bien faire. La patrie de l'éternelle vérité et de l'éternelle beauté est aussi la patrie de la paix.

Associés et correspondants de l'Institut de France, vous n'emporterez pas seulement d'ici le souvenir des chaleureuses sympathies qui vous ont accueillis. Nous emporterons tous, de cette réunion fraternelle, un redoublement d'amour pour la paix, pour les sciences qui la fécondent et pour les arts qui l'embellissent; et nous travaillerons, chacun dans notre coin préféré de l'atelier universel, à la prospérité de la maison, c'est-à-dire au bonheur de l'humanité.

"BARISÀL GUNS" AND "MIST POUFFERS."

In the delta of the Ganges, dull sounds, more or less resembling distant artillery, are often heard. These are called "Barisàl guns"; but I do not know the meaning of the term.[1] The object of this note is to draw the attention of the readers of NATURE to this mysterious phenomenon, and to the similar "mist pouffers" of the Belgian coast.

My attention was for the first time drawn to the subject some days ago by a letter from M. van der Broeck, Conservator of the Museum of Natural History of Belgium. He writes[2] of certain "curious aerial or subterranean detonations, which are pretty commonly heard, at least, in Belgium and in the north of France, and which are doubtless a general phenomenon, although little known, because most people wrongly imagine it to be the sound of distant artillery.

"I have constantly noticed these sounds in the plain of Limburg since 1880, and my colleague of the Geological Survey, M. Rutot, has heard them very frequently along the Belgian coast, where our sailors call them 'mist pouffers' or fog dissipators.

"The keeper of the lighthouse at Ostend has heard these noises for several years past: they are known near Boulogne, and the late M. Houzeau spoke of them to my friend M. Lancaster. More than ten of my personal acquaintances have observed the fact.

"The detonations are dull and distant, and are repeated a dozen times or more at irregular intervals. They are usually heard in the day-time when the sky is clear, and especially towards evening after a very hot day. The noise does not at all resemble artillery, blasting in mines, or the growling of distant thunder."

M. van der Broeck, after referring to the "Barisàl guns," says that he was disposed to regard the noises as due to some peculiar kind of discharge of atmospheric electricity. "But my colleague M. Rutot believes the origin to be internal to the earth. He compares the noise to the shock which the internal fluid mass might give to the earth's crust."

Mr. Clement Reed has informed M. van der Broeck that he believes similar noises are heard on Dartmoor, and in some parts of Scotland. I was not previously aware of anything of the kind in these islands.

Before any systematic observations are undertaken, it will be useful to form some general idea of the frequency of these sounds and of their geographical distribution.

Will any of the numerous readers of NATURE in various parts of the world give us an account of their experiences in this matter? G. H. DARWIN.

NOTES.

The Municipal Council of Paris have decided to erect a statue to Sir Isaac Newton. We cannot imagine the London County Council paying a similar graceful tribute to the greatness of one of France's renowned investigators, say Laplace or Lavoisier, but we dare to suggest that the action of the Paris Municipality ought to be reciprocated.

Munificent gifts to science and education continue to be reported from America. *Science* states that the Spring Garden Institute of Philadelphia has received £20,000 from the heirs of Samuel Jeanes, who supported the Institute with great generosity during his lifetime; Earlham College at Richmond, U.S., has

[1] T. D. La Touche, Brit. Assoc. Rep. 1890, p. 800.

[2] I give a free translation and abridgement of the letter.

received £5000 from Mr. M. H. White and Mr. F. T. White, in memory of their father; a new laboratory, built at a cost of £8000, is almost completed for the departments of bacteriology, histology, and pharmacy in the Medical College of the University of Minnesota; and by the will of Colonel W. L. Chase, £1000 is bequeathed to Harvard College to establish a scholarship in the medical school.

DURING the recent Zoological Congress, at one of the meetings of the Section of Comparative Anatomy and Embryology, Prof. A. Kovalewsky bore testimony to the greatness of Huxley in words of which the following is a translation: "In the list of men of science who expressed their intention to take part in our Congress will be found the name of Thomas Huxley; but death has prevented him from being among us. In the person of Huxley, science has sustained a great loss. We do not know any other investigators of our century who had the talent of foresight to such an extent as Huxley. It was he who, properly speaking, founded modern embryology by demonstrating the homology of the germinal layers of Vertebrates with the ectoderm and endoderm of Cœlenterates. It was he who supported Darwin in the publication of the fundamental work on the origin of species, and it was he who was the fervent propagator of the views therein contained. The two names of Darwin and Huxley have built up the story of the scientific world."

THE following gentlemen have been recommended for election as the Council and officers of the London Mathematical Society at the annual meeting to be held on November 14:—President, Major P. A. Macmahon, F.R.S.; Vice-Presidents, Prof. M. J. M. Hill, F.R.S., M. Jenkins, A. B. Kempe, F.R.S.; Treasurer, Dr. J. Larmor, F.R.S.; Secretaries, R. Tucker and A. E. H. Love, F.R.S. Other members—H. F. Baker, G. H. Bryan, F.R.S., Lieut.-Colonel A. J. Cunningham, Prof. Elliott, F.R.S., Dr. Glaisher, F.R.S., Prof. Greenhill, F.R.S., Dr. Hobson, F.R.S., Prof. W. H. H. Hudson, and F. S. Macaulay. It will be seen that Mr. Jenkins, after thirty years' service, has retired from the office of Secretary, on the score of his delicate state of health. The Society held its first meeting on January 16, 1865, and on the retirement of Mr. H. M. Bompas (November 20, 1865), Mr. Jenkins was requested to act as Secretary until the annual general meeting (January 15, 1866), when he and the late G. C. de Morgan were elected joint Secretaries.

NEXT Sunday will be Museum Sunday—the fourth arranged by the Sunday Society. On that day special sermons or discourses will be given by many leading men in London and the provinces, in support of the Society's object, viz. the opening of museums, art galleries, libraries, and gardens on Sundays. The cause is a righteous one, and deserves every support. A number of special exhibitions will be held in the afternoon of Sunday, and these, together with the museums and other places of interest which will be open, make a fairly extensive list of institutions opened in the manner advocated by the Society. The list clearly indicates that the public opinion of the country is really on the side of a rational observance of the weekly day of rest.

THE death is announced of Prof. H. Hellriegel, in his sixty-fourth year. His investigations in the domain of agricultural science produced many valuable results, and it was his researches that led to the discovery of the fixation of free nitrogen by leguminous plants, through the medium of micro-organisms in the root nodules.

THE death of Dr. Robert Brown deprives science of one of her most popular exponents. Dr. Brown was born at Campster, Caithness, in 1842. He studied in the University of Edinburgh, and afterwards in the Universities of Leyden, Copenhagen, and Rostock, receiving from the latter the degree of Doctor of Philosophy. In 1861 he visited Spitzbergen, Greenland, and the western shores of Baffin's Bay, and made a number of valuable observations. Between 1863-66 he travelled for scientific purposes in many of the least-known parts of America, and some of the Pacific Islands, from the West Indies and Venezuela to Alaska and Behring Sea Coast, as botanist of the British Columbia Expedition and commander of the Vancouver Island Exploring Expedition, during which he introduced various new plants into Europe, and charted all the interior of Vancouver, then unknown. In 1867 he visited Greenland, making, with Mr. E. Whymper, the first attempt by Englishmen to penetrate the inland ice, and formed those theoretical conclusions regarding its nature, afterwards confirmed by Nansen and Peary. Dr. Brown afterwards travelled extensively in the Barbary States of North Africa. Settling down in Scotland he was successively lecturer on geology, botany, and zoology in the Royal High School, Edinburgh, and Heriot Watt College, Edinburgh, the Mechanics' Institution, Glasgow, and elsewhere. He was an honorary or ordinary member of many learned societies in this country, in America, and on the continent. In 1876 he removed to London, in order to devote himself entirely to literary work, and for the greater part of the period, from that time to his death, was on the editorial staff of the *Standard*. He was the author, or part author, of about thirty volumes, and of a large number of scientific memoirs, articles, and reviews.

THE thirty-fourth annual meeting of the Yorkshire Naturalists' Union was held yesterday at York Museum, and the presidential address was delivered by Dr. R. Braithwaite, on "The Study of Mosses."

MR. ARCHIBALD DENNY, of Dumbarton, has accepted the presidency of the Institution of Junior Engineers, in succession to Mr. Alexander Siemens, and will deliver his presidential address on Friday evening, November 1, at the Westminster Palace Hotel; Prof. A. B. W. Kennedy, Past-President, in the chair.

THE Epping Forest Free Local Museum, established by the Essex Field Club in Queen Elizabeth's Lodge, Chingford, will be declared open next Saturday afternoon, by Mr. R. C. Halse, Chairman of the Epping Forest Committee of the Corporation of London. Short addresses on the subject of local museums will be given by Mr. A. Smith Woodward, and others.

THE Session 1895-96 of the Royal Geographical Society, for the evening meetings, will commence on November 11, when an account of the progress of the Jackson-Harmsworth Arctic Expedition will be given by Mr. A. Montefiore. On November 25, a paper on the Fœroe Islands will be read by Dr. Karl Grossmann; exploration in the Central Alps of Japan will be described by the Rev. Walter Weston on December 9; and movements of the earth's crust, by Prof. John Milne, F.R.S., on January 6. Other papers which may be expected after Christmas are the following: Journey across Tibet, by St. George R. Littledale; exploration in the Alps of New Zealand, by E. A. Fitzgerald; our knowledge of the oceans, by Dr. John Murray; the geography of the English lake district, by J. E. Marr, F.R.S.; the cañons of Southern Italy, by R. S. Günther; British Central Africa, its geography and resources, by Alfred Sharpe. The following subjects, among others, will be submitted for consideration and discussion at the special afternoon meetings:—The construction and uses of globes, by J. Y. Buchanan, F.R.S.; the struggle for life in the North Polar region, by A. Trevor-Battye; an attempt to reconstruct the maps of Herodotus, by J. L. Myres. Under the joint auspices of the Society and the London University Extension, Mr. H. J. Mackinder is giving a course of twenty lectures on the principles of geography, at Gresham College.

The *Weekly Weather Report* of the 20th inst. shows that the temperature over the British Islands during the week was abnormally low for the time of year, the deficit ranging from 4° in the Channel Islands, and 6° in the east of England and north of Ireland, to 8° in the north-west of England and the south of Ireland. The lowest shade readings were recorded towards the end of the week, and ranged from 18° in the south-west of England to 21° in the south of England and 22° in the Midland counties. The continuous occurrence of frost for several nights in the neighbourhood of London during the current month of October has exceeded any previous record in that month at Greenwich during the last fifty years.

A description of a luminous cloud, observed at Mojanga, Madagascar, on September 27, by Mr. Stratton C. Knott, H.M. Vice-Consul, has been forwarded to us by Mr. R. H. Scott, F.R.S. The phenomenon was seen at 8.20 p.m. as a narrow streak of what appeared more like mist than cloud. It came out of a cumulus cloud in the south, a few degrees above the horizon, and extended through the tail of Scorpio across two-thirds of the sky, which was quite clear excepting some cumulus on the southern and eastern horizon. The streak travelled at a rapid rate eastwards, but its base seemed to be stationary: as it crossed the moon, it caused a sort of double corona. As the cloud got lower on the eastern horizon, although always maintaining the same length, some cumulus passed under it, partly obscuring it, and a few minutes later the streak was lost altogether in the cumulus on the eastern horizon. At the time of the observations the weather was perfectly calm, but soon after this streak had passed, cumulus commenced to ascend from the eastward, and the sky soon became nearly overcast.

The polarisation of the light emitted by incandescent bodies has not yet been fully investigated. Arago, indeed, made some experiments on incandescent iron, platinum, and glass, but these were only qualitative, and did not extend to liquids. Mr. R. A. Millikan publishes, in the *Physical Review*, an account of some careful tests of light emitted by glowing solids and liquids with a view to discover the laws of its polarisation. This phenomenon is exhibited strongly by incandescent platinum, silver, and gold, and by molten iron and bronze. A somewhat feebler polarisation is shown by copper, brass, lead, zinc, and solid iron. The most significant result is that polarisation is minimum with rays emitted normally to the surface, and maximum at a grazing emission. This indicates that the vibrations take place in a plane at right angles to the emitting surface. To show the phenomenon at its best, a smooth surface is essential. Glass and porcelain also emit polarised light, but to a lesser amount. Fluorescent bodies do the same, so that evidently a high temperature is not necessary. In the case of uranium glass it is the green reflected light which is polarised, and not the blue incident light diffused from the surface.

The main facts of Lieut. Peary's work in North Greenland are described by Prof. R. D. Salisbury in *Science* of October 11. Prof. Salisbury was one of the party which relieved Lieut. Peary, the other members being Mr. Emil Diebitsch, Dr. J. E. Walsh, Mr. T. Boutillier, and Prof. L. L. Dyche. During his Arctic residence, Lieut. Peary mapped a considerable stretch of the coast of West Greenland from Cape Alexander on the north to Cape York on the south, and his results show a number of remarkable differences with earlier charts of the same region. His map locates the position of nearly one hundred glaciers, where but ten were represented on the published chart. In addition to the map, Mr. Peary kept a series of meteorological records, and made observations of the behaviour of [illegible], and in this way has come into possession of facts which are not without significance in connection with the problems of glaciology. He made careful measurements of the rate of motion of one of the most active glaciers of the region, and carried them through a sufficiently long period of time to give them especial value. He took back to the United States two large and choice meteorites from the coast east of Cape York, and these will undoubtedly prove of interest. His studies of the Eskimos of North Greenland will, when published, form an important contribution to ethnology.

So far as concerns the results accomplished by the members of the Peary relief party of this year, Prof. Dyche was successful in getting large numbers of birds and mammals at various points along the coast. He also secured an abundant supply of walruses, reindeer and seals, and a smaller number of narwhals, and saw much of the west coast of Greenland between latitude 64° and 78° 45′, at close enough range to study its geographic features to advantage. Stops were made near the parallels of 67°, 69°, 70°, and at many points between 75° 45′ and 77° 45′. At all these points geographical and geological studies were carried on. The eastern coast of America was also seen for a considerable distance, especially from Ellesmere Land south to 71° 30′, and most of the coast of the island of Disco. Prof. Salisbury, who accompanied the party in order to study glacial geology, observed in detail many glaciers between 75° 45′ and 77° 45′ on the Greenland coast, and made some determinations of significance concerning glacier motion. A considerable body of evidence was gathered touching the former extension of the ice cap of Greenland. Determinations were also made at several points concerning recent changes of level of the land.

A recent number of the *Pioneer Mail*, published in Allahabad, contains an interesting article on immunity from scorpion and snake venom. Much attention has been directed in India to the experiments, which have lately been so successfully carried out, on immunity to snake-bites artificially induced by the introduction of gradually increasing doses of the venom into the system. The writer of the article in question does not regard this achievement as any really new discovery, being convinced that the traditional immunity claimed to be possessed by the Indian snake-charmers is simply due to the fact that they have frequently been accidentally bitten by cobras and karits, and having survived the first attack experienced no evil effects from the subsequent bites. This he states as the result of his personal acquaintance with many Madari Jogis and Fakirs, some of whom he knew had been bitten as many as five times. It appears, however, that cases of reputed immunity to scorpion stings are also well known, and one of these he had the opportunity of himself carefully testing. Hearing of a Mahomedan Fakir who had established a reputation for himself in this respect, he determined to investigate the case, and banish, if possible, all chance of trickery and deception being practised. He therefore dug up the scorpions himself, and these formidable creatures he describes as being from 5 to 7 inches long, with claws on them like lobsters. These scorpions the Fakir was told to irritate (not by pinching the end of the tail, which is a well-known way of preventing them stinging!), but by touching them on the part of the body indicated: the result was that each one of them stung him strongly enough to draw blood, but the man was apparently none the worse. "There could be no doubt," he writes, "as to the perfect genuineness of the exhibition." This incident should encourage M. Calmette to continue his experiments on artificially inducing immunity to the sting of scorpions by means of gradual doses of the scorpion venom. It is to be hoped that the successful investigations which have so far been made on artificially procuring immunity to snake-bites, may obtain the official recognition which they deserve, and that such immunity may not in the future be confined to the selected few or so-called charmed individuals.

In a lecture recently delivered by Dr. W. J. van Bebber, at Lubeck, and printed in the *Annalen der Hydrographie und Maritimen Meteorologie* for September, he discusses the possible means of improving storm-warning signals. As Dr. v. Bebber has charge of the weather service at the Deutsche Seewarte, his views on the subject carry considerable weight. He points out that notwithstanding constant exertions to place weather prediction on a sound and trustworthy basis, the solution of the question remains in a somewhat unsatisfactory condition. He makes the following suggestions for the furtherance of the object in view, most, if not all, of which have already been discussed at various meteorological conferences, and have fallen through on the score of expense or other hitherto insuperable difficulty:—(1) Extension of telegraphic communication westward (Färoe, South Greenland, &c.). This proposal was advocated by the late Captain Hoffmeyer. (2) Acceleration of exchange of telegrams, by the introduction of the "circuit-system." By this means the telegrams in America are received, and warning messages despatched within two hours of the time of taking observations. (3) More frequent information, by means of telemeteorography, or the connection of self-recording instruments with central offices. The practicability of this method has been put to test in the Netherlands, and the subject was recently discussed by the International Meteorological Committee at Upsala. (4) Exchange of telegrams between neighbouring signal stations; this plan has been found to work successfully in Germany and America, and by its means more recent information is obtained by the seafaring community as to the sudden approach of stormy weather. (5) The popularisation of weather knowledge among the public by means of weather charts, and (6) the preparation of an atlas of types of weather. The number of charts required would be at least 500 or 600. This subject has been suggested by Mr. Abercromby and others.

A new method of measuring the resistance of an air-gap during the passage of a spark has been devised by M. Victor Biernacki, and is described in the current number of the *Journal de Physique*. In the case of a Hertzian resonator in unison with an exciter, the forced vibrations and the natural vibrations of the resonator (the presence of which, according to Poincaré and Bjerkness, explain multiple resonance) have the same periodic time, and according to Bjerkness's theory these two vibrations are in oppose phase. In order that these two vibrations may entirely destroy each other, it is necessary that they be equally damped—that is to say, that the resistance of the exciter and resonator should be equal. The author has verified this consequence of the real presence of these two sets of vibrations in the resonator, by steadily increasing the resistance of the resonator, starting with a resistance less than that of the exciter. In this way he has succeeded in entirely destroying the vibrations in the resonator, and according to theory at this moment the resistances of the exciter and resonator must be equal. Since these had the same dimensions, and were made of the same material, but the spark-gap in the exciter was replaced by a liquid resistance R, it follows that the value of R, which corresponds to the completed extinction of all vibrations in the resonator, is equal to the resistance of the spark-gap in the exciter. The resistance R consists of a glass tube filled with a solution of copper sulphate of various strengths. A Geissler tube or a bolometer is employed to indicate the presence of the vibrations in the resonator. As the dilution of the sulphate of copper solution is increased, the vibrations in the resonator decrease in intensity. These die out, and on further dilution reappear. For a spark-gap of 1 cm. the resistance R varied between 300 and 800 C.G.S. units. With a spark-gap 0·4 m.m. long, however, the resistance is found to be between 1200 and 1500 C.G.S. units. This increase of the resistance as the spark diminishes is very curious; but it is important to notice that the decrease in the length of the spark is accompanied by a change in other properties of the spark. When the terminals of the spark-gap are near together it is very difficult to obtain a straight and white spark, the spark generally being slightly violet in colour and ramified in appearance. With a longer spark-gap, however, it is much easier to obtain a spark which is white in colour and non-ramified, and which passes with a sharp noise. It is a spark of this latter character which Hertz found to be best suited to his classical experiments, and the fact established by the author that such a spark really offers less resistance than a short violet spark, affords an explanation of Hertz's observation.

With the title "The People's Stonehenge," a slim little pamphlet, by Mr. J. J. Cole, has been published by Mr. J. Doney, Sutton, Surrey. The pamphlet contains ten reproductions from photographs of the objects at Stonehenge; and these, with the short descriptive text which accompanies them, brings out the points of interest in the most wonderful of our archæological remains.

Astronomers should be grateful to Messrs. W. Wesley and Son for the excellent catalogue of works on astronomy just published as No. 124 of the Natural History and Scientific Book Circular. The classification is very elaborate, the books being arranged under no less than twenty-four headings. In each section the books follow the alphabetical order of authors' names. Both the arrangement of the sections and the divisions adopted are admirable, and reflect great credit upon the compilers. Bibliophiles well know that a bookseller's catalogue is a mine of information, and they will be joined by astronomers in appreciation of the efforts of Messrs. Wesley and Son to produce a full and accurate list of works on celestial science.

The *Proceedings* of the American Philosophical Society for January, 1895, reached us at the beginning of this week. Among other papers contained in it we notice a description (with four plates) of an old "Horologium Achaz," or Dial of Achaz, by Mr. J. F. Sachse; a paper on "The Significance of the Jugal Arch," by Mr. D. D. Slade; a note proving that thin leaves of gold, similar to those exhibited by Mr. J. W. Swan at the Royal Society in June 1894, were produced by Mr. A. E. Outerbridge seventeen years ago (on this matter, see Mr. Outerbridge's claim for priority in Nature, vol. li. p. 608, 1895); a paper by Dr. D. G. Brinton on the "Protohistoric Ethnography of Western Asia," and the "Fourth Contribution to the Marine Fauna of the Miocene Period of the United States," by Prof. E. D. Cope.

Messrs. Macmillan have just issued the first part of the "History of Mankind," by F. Ratzel, in which the learned author states what the task of ethnography is, and describes the situation, aspect, and numbers of the human race, together with a series of preliminary observations on the rise and spread of civilisation, religion, language, &c. Where possible he illustrates his remarks by pictures of genuine "savage" remains, and his theories have usually a good substratum of fact. It is, of course, too early to pass a final opinion on the work: but we believe that it supplies a want among the increasing number of people who need a popular history of the beginnings of the human race, and an intelligible account of the conditions under which our primitive ancestors lived. The part before us is printed in good type on excellent paper, and contains a coloured plate of a Bosjesman family, and a map of North and South America, besides several illustrations scattered throughout the text.

Dr. A. B. Meyer has sent us a memoir (*Abh. u. Ber. des K. Zoolog. u. Anthropol. Ethn. Museums zu Dresden* 1894–95) on a

Brown Chimpanzee. The Chimpanzee described and figured in it is a young female living in the Zoological Gardens at Dresden, remarkable for its reddish brown hair, projecting eyes, and very bright-coloured skin. Dr. Meyer discusses at some length the numerous species, sub-species, and varieties of the Chimpanzee that have been proposed by various authors, and decides that his "Brown Chimpanzee" can be referred to none of them. It may be quite true that no one has previously described such a brown form of the Chimpanzeee, but nearly all mammals, especially the Quadrumana, are subject to lighter variations in colour, and we see no reason why this should not be the case with the Chimpanzee. It would seem, therefore, that Dr. Meyer has done well in not giving his Brown Chimpanzee a new scientific name. It appears that nothing is known of the history of the specimen, nor of its exact locality.

The third and concluding portion of Kubary's monograph of the ethnography of the Caroline Archipelago is now published under the editorship of Herr J. D. E. Schmeltz, who has, as usual, spared no pains to bring out the memoir in a way which its value demands. The complete work consists of 306 pages and fifty-five plates; many of the latter are coloured. They are executed by Trap, which is a sufficient guarantee of their excellence. It is to the famous but ill-fated Museum Godeffroy that we owe the inception of this investigation. At a later date Kubary was connected with the Kgl. Museum fur Volkerkunde in Berlin. The present section, which deals with house- and canoe-construction in the Pelau Islands, maintains the level of conscientious care and minute detail which characterised the two former parts. The structure of the houses and canoes is illustrated to scale by drawings in plan, elevation, and section; and details of fastenings and joinery are given on a larger scale. We have thus all the information necessary to understand structural details, which latter are too often lacking in the descriptions and illustrations of travellers. Some houses are richly decorated with carved and painted ornamentation; but unfortunately Kubary was not impressed with the importance of this branch of ethnography, and so we are left in ignorance as to the significance of the figures and patterns. What a pity it is that the ethnography of our Possessions and Protectorates in various parts of the world is not investigated and published in such a manner as this!

We have received from Mr. J. Eliot, F.R.S., Meteorological Reporter to the Government of India, parts viii. and ix. of vol. v. of "Indian Meteorological Memoirs," containing the discussion of hourly observations made (1) at Deesa, a military station in the Palanpur State on the Banas River; and (2) at Kurrachee, the Port of Sind. The latter station is about three miles from the sea, and has a most complete exposure. The period embraced is 1875–93, and forms part of the proposed discussion of the observations recorded at twenty-five observatories. For each station the mean observed hourly values of the various elements, and the differences from the mean of the day, have been calculated, and from these the diurnal variations have been resolved into four component harmonic oscillations by the application of Bessel's formula, while the epochs and values of the diurnal maxima and minima have been computed by the method used by Dr. Jelinek, to the second approximation. The investigation of the materials at each station is of itself a most laborious and thorough piece of work, and the complete discussion will be probably unequalled in magnitude. The importance of the whole investigation can scarcely be over-estimated, and when the results are collated they cannot fail to throw much light upon the causes which underlie the periodic variations over this area, and their dependence on various physical and local conditions.

Xylose, like arabinose, gives two optically active stereoisomeric acids on treatment with hydrocyanic acid and subsequent hydrolysis. Of these, gulonic acid has long been recognised; the second, idonic acid, has recently been isolated, and its derivatives prepared by Emil Fischer and Irving Wetherbee Fay (*Berichte*, 1895, No. 14, p. 1975). The series is remarkable as containing the last missing members of the mannitol group of acids, sugars, and alcohols. The names—idonic acid, idose, iditol, and idosaccharic acid—assigned to these substances have been derived from "idem," and given on account of the symmetrical geometrical formulæ expressing their constitution. From the formula of l-idose,

$$\begin{array}{c} \quad\quad\;\; H \;\; OH \;\; H \;\; OH \\ CH_2OH\,.\,C\,.\,C\,.\,C\,.\,C\,.\,COH \\ \quad\quad\;\; OH \;\; H \;\; OH \;\; H, \end{array}$$

it is evident that hydroxyl and hydrogen are similarly related to each of the asymmetrical carbon atoms, and that only the *same* product, racemic acid, and no inactive tartaric acid can be produced by oxidation wherever the molecular chain is broken; in this respect a remarkable contrast to the other hexoses being shown. From the product of the action of hydrocyanic acid on xylose, gulonic acid was separated by repeated crystallisation of the lactones; the syrupy dark liquid resulting on evaporation of the mother liquor was diluted and treated with brucine. The product on evaporation and addition of a large quantity of alcohol gave a crystalline mass of brucine idonate. When purified and recrystallised from methyl alcohol it formed colourless prisms, or long rectangular plates, which melted with decomposition between 185° and 190° (corr.). The acid was prepared from the brucine salt by addition of barium hydrate and subsequent decomposition of the barium salt with sulphuric acid. Ultimately a relatively good yield of idonic acid and its lactone was obtained as a colourless syrup, which dissolved easily in water, and with difficulty in alcohol, and was insoluble in ether. 0·5 gram dissolved in 3·5 grams of water gave a rotation of 5·2° in a decimeter-tube. The normal idonates of calcium, barium, cadmium, and lead are amorphous and very easily soluble in water. A characteristic cadmium double salt, $(C_6H_{11}O_7)_2Cd.CdBr_2.H_2O$, crystallises in fine, colourless needles. The corresponding sugar, l-idose, was prepared from the syrupy mixture of idonic acid and its lactone by reduction with $2\frac{1}{2}$ per cent. amalgam after dilution with ten times its volume of ice-cold water. The sugar was isolated in the usual way as a syrup, which could not be completely purified through lack of material. A 10 per cent. sterilised solution did not ferment with yeast. The osazone, prepared as usual, could not be distinguished from gulosazone. The alcohol of this series, l-iditol, was obtained by the further reduction of idonic acid by sodium amalgam, first in acid, and finally in alkaline solution. It was purified by formation of the benzaldehyde compound, recrystallised from acetone in colourless needles of the composition $C_6H_8O_6(CH.C_6H_5)_3$. The purified compound, on treatment with sulphuric acid and alcohol, gave the alcohol as a colourless syrup very easily soluble in water. The idosaccharic acid was formed from idonic acid by treatment with nitric acid, and yielded crystalline calcium and copper salts.

The additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Sir Egbert Sebright, Bart.; a King Parrakeet (*Aprosmictus scapulatus*) from Australia, presented by Mr. George Cawson; two White Storks (*Ciconia alba*), European, presented by Sir Charles Payne, Bart.; an Ortalan Bunting (*Emberiza hortulana*), European, presented by Mr. H.

C. Martin: two Hybrid Widgeons (between *Mareca penelope* and *Anas boschas*), bred in England, presented by Mr. Wellesley Taylor; a Cape Viper (*Causus rhombeatus*), two Rufescent Snakes (*Leptodira rufescens*) from South Africa, presented by Mr. J. E. Matcham; a Great Kangaroo (*Macropus giganteus*) from Australia, deposited: two Hunter's Spiny Mice (*Acomys hunteri*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

RUTHERFURD'S STELLAR PHOTOGRAPHS.—The pioneer work of the late Dr. Rutherfurd in photographic star charting is gradually assuming a form which gives the results a high scientific value. In 1890, Dr. Rutherfurd presented his original negatives, many of them taken more than twenty years ago, to the Columbia College Observatory, New York, together with some thirty volumes of measures of certain star photographs, and Prof. J. K. Rees was authorised to arrange for the discussion of the photographs. After Dr. Rutherfurd's death in 1892, his son, Rutherfurd Stuyvesant, generously provided funds for continuing the reduction and publication of the measures. The results obtained for the stars of the Pleiades group, and for the stars about β Cygni have already been published, as well as an investigation of the parallaxes of μ and θ Cassiopeiæ. To these are now added two papers giving full details of an investigation of the parallax of η Cassiopeiæ, and of the reduction of positions of sixty-two stars in the neighbourhood (*Ann. New York Acad. Sci.*, vol. viii. 301, 381). Using three pairs of comparison stars, the parallax deduced for η Cassiopeiæ is 0″·443 ± 0″·043; or, taking six pairs, 0″·465 ± 0″·044 (see NATURE, vol. lii. p. 61). In view of the difficulty of getting comparison stars suitably situated either with respect to position angle, or distance, it was considered desirable to take a larger number than usual, and hence six pairs were reduced, being all that were sufficiently impressed on the plates in both seasons of the year. Only the three pairs which lead to the first-named value, however, are so situated with reference to the parallactic ellipse as to give good coefficients for the parallax.

RADIAL VELOCITIES OF SATURN.—The recent spectroscopic investigations of the velocities in the Saturnian system furnish an admirable illustration of the accuracy at present attainable in this department of astronomical research. Prof. Keeler, M. Deslandres, Prof. Campbell, and Dr. Belopolsky have each in turn directed their attention to the planet, and the following table brings together the different results obtained, and compares them with the computed velocities:—

	Equatorial velocity of planet.	Excess of velocity for inner edge of ring.
Keeler ...	10·3 km. per sec. ...	3·6 km. per sec.
Deslandres ...	9·4 ,, ...	4·7 ,,
Campbell ...	9·77 ,, ...	3·13 ,,
Belopolsky ...	9·4 ,, ...	5·5 ,,
Computed ...	10·3 ,, ...	3·9 ,,

It thus appears that in the hands of competent observers, the photographic methods now employed for the determination of velocities along the line of sight may be relied upon to give values which are correct to within one kilometre per second; while for results depending upon the measurement of more than one velocity, a little greater latitude must be allowed.

In reply to the objection of M. Deslandres and Prof. Seeliger, that the spectroscopic results do not strictly prove the meteoritic constitution of the ring, Prof. Keeler has pointed out that any other explanation which is consistent with them can only be regarded as artificial, or inherently improbable (*Ast. Nach.* 3313). If the ring were composed of concentric solid rings, a line in the spectrum would be made up of short straight lines, like an end view of a flight of stairs. Prof. Keeler does not consider his own photographs capable of showing more than ten such subdivisions, for if the number were greater than this, the step-like structure of the lines would be destroyed by unavoidable errors in guiding; but up to a certain point the effect would still be apparent in the widening of the lines. He finds, however, that the definition of the lines in the spectrum of the ring is less affected by guiding errors than that of the lines of the planet, as might be expected if the lines were smooth curves such as would be produced in the case of a meteoritic ring.

THE CAPE OBSERVATORY.—Dr. Gill's report of the work done at the Cape Observatory during 1894 has been distributed. It opens by pointing out that the chief desideratum in astronomy during the past decade has been an adequate provision for the study of astrophysics in the southern hemisphere. As the readers of NATURE are aware, Mr. Frank McClean, F.R.S., has given to the Cape Observatory a splendid equipment for such work, so the need has been met, and a harvest of results may be looked for as soon as the instrument is erected. With reference to this generous gift, the report says that the telescope will have a photographic object-glass of 24 inches aperture and 22½ feet focal length, and be provided with an objective prism of the same aperture having a refracting angle of 7½°. Mounted parallel to this there will be a visual telescope of 18 inches aperture and of the same focal length as the photographic telescope. The equatorial mounting will have complete circumpolar motion for within 30° of the zenith; and will be sufficiently elevated to allow of a slit spectroscope suitable for determining motion in the line of sight. Such a spectroscope will also be provided by Mr. McClean, together with an observatory of light construction. The instrument has been for some time under construction by Sir Howard Grubb, and will probably be completed before the end of 1896.

Among the work done with the astro-photographic telescope, we notice that, after rejecting all plates of insufficient exposure, or which are otherwise faulty, only 70 of the plates for the Catalogue, out of 1632 areas assigned to the Cape, remain to be done. Of the chart plates, 263 have been passed as satisfactory.

Measures of the diameters of the photographic discs of a variable star in Vela, together with those of nine comparison stars, prove the former to be a variable of the Algol type, its period being about 5d. 22h. 24m. 4s. A complete discussion of the light curve and period will shortly be undertaken.

The researches on the solar parallax have been carried forward, three sections of the work, on the observations of the minor planets Victoria and Sappho, having been passed through the press. The manuscript of the definitive discussion of the observations of Victoria has been sent to the printers; while the computations of the solar parallax from the observations of Sappho and Dr. Elkin's reductions of the observations of Iris are completed.

THE INSTITUTION OF MECHANICAL ENGINEERS.

AN ordinary general meeting of the Institution of Mechanical Engineers was held on the evenings of Wednesday and Thursday, October 23 and 24, at the Royal United Service Institution, Whitehall, the Council having lent their new theatre for the purpose. The building of the Institution of Civil Engineers, where the Mechanical Engineers have held their London meetings for years, is now in process of rebuilding. It is to be hoped, however, that the Institution of Mechanical Engineers will, before long, have their own premises.

There were three papers down for reading on the first day of the meeting:

"The Electric Lighting of Edinburgh," by Henry J. Burstall.

"Report on the Lille Experiments upon the Efficiency of Ropes and Belts for the Transmission of Power," translated by Prof. David S. Capper.

"Observations on the Lille Experiments upon the Efficiency of Ropes and Belts for the Transmission of Power," by Prof. David S. Capper.

The chair was taken on each evening at 7.30, by Prof. Alexander B. W. Kennedy, F.R.S. On the first evening Mr. Burstall's paper was read and discussed.

The electric lighting of Edinburgh is in the hands of the Corporation. It was decided upon in 1893, when the work of designing and superintending the scheme was entrusted to Prof. Kennedy, the President of the Institution. From an electrical point of view the city consists of two districts. In one the houses are close together, and the demand for light may be expected to be fairly concentrated; in the other it will be more scattered. Having regard to the different districts to be served, and taking into account all the local circumstances, it was decided, after comparison of the various systems of supply and distribution which could be used, to adopt a low tension three-wire system

for the central and northern district, and an alternating-current high tension system for the southern and eastern district, both systems being worked from one central station, and under the same control and management. A good site was found for the central station between the Caledonian Railway and Dewar Place.

The boiler-house is designed to contain seventeen boilers, of which at present only six are in place. They are of the dry-backed marine type, each 10½ feet mean diameter and 12 feet long, with two Purves flues 3¼ feet inside diameter, and 166 tubes of 3 inches internal diameter. The boilers are of steel with wrought-iron tubes. On the top of the boilers are fitted super-heaters, each having two nests of tubes enclosed between the top of the boiler shell and a fire-brick casing above. Each consists of thirty-two vertical flat coils of wrought-iron tube 1½ inches diameter. Sinclair's mechanical stokers are fitted to each boiler, and are driven by an electric motor. The main steam pipe forms a complete ring round the present boilers. This ring joins the engine-room main at two points, and is provided with valves, so that the failure of any one pipe will put only the corresponding boiler out of use. The pump-room contains at present one duplex steam pump and two three-throw pumps driven electrically, each pump specially designed to run with a large range of speed, and for this purpose can be connected with either the 230-volt or the 115-volt mains. A Kennedy water meter is connected with one range of feed pipes, so that the whole of the water going to the boilers can be measured. In the pump-room is placed the electric motor for driving the mechanical stokers with its counter shaft. The coal brought in the railway trucks is at present stored in the east end of the boiler-house; on the station being extended, the coal will be stored over the boiler-house, and let down through shoots to the mechanical stokers. In designing the plant at present in the boiler-house, provision for extensions has been kept in mind, and the arrangements are such that new plant can be added at any time.

The engine-rooms are side by side, forming really one room divided by a line of columns which carry the roofs and the beams for the travelling cranes. The engine-room next the boiler-house is reserved for the low-tension plant, the other contains the high-tension plant. A platform, raised 4 feet above the engine-room floor level, runs the whole way across the west end of both engine-rooms; and on this are placed the switchboards and regulating gear for both the low- and high-tension systems. The machinery at present in the low-tension engine-room consists of eight engines, four of 100 I.H.P., two of 250 I.H.P., and two of 360 I.H.P., with their dynamos: and provision is made for eight more engines of 360 I.H.P., in the future. All are Willans central-valve engines driving their dynamos direct. All the dynamos are two-pole shunt-wound machines with drum armatures, all wound to give 270 volts, except two which are driven by two 100 I.H.P. engines: these two are wound to give 135 volts, being used as balancing machines on the three-wire system. The steam-piping forms, with part of the boiler-house ring, a complete ring round the low-tension engine-room, and is connected with the boiler-house ring at two points. The main ring is 8 inches internal diameter throughout. The straight lengths are of steel, with thick flanges screwed and brazed on; the tee pieces and valve boxes are of cast-iron; and the bends of copper with steel flanges. All bends are of large radius, and no expansion joints are used or required. The engines are erected in pairs, and are connected with the main ring by two long copper bends. The pipes are slung by long rods from brackets fixed on the walls or columns, so as to allow free movement. The main exhaust pipes are of cast iron, and are led through a Berryman feed heater, in the boiler house to the chimney. Provision is made for three more heaters when required. The whole of the machinery is fixed on a concrete foundation block 7½ feet thick, which is separate from the foundations of the walls.

The main leads from the dynamos are drawn through curved wrought-iron pipes let into the concrete, into chases in the centre of the engine foundation block, along which they are carried to the channel under the switchboard platform. The leads from the field winding off the machines are also carried in the same manner to their regulating resistances; the switches for these resistances are fixed upon the handrail on the platform in front of the switchboard, the leads from the resistances being brought up through the posts of the handrail. The switchboard, and the whole of the apparatus for regulating the dynamos and the mains used for the distribution of the current, are placed on one platform, and are directly under the eye of the engineer in charge. The switchboard consists of seven slate panels, each about 7 feet high, and stands 4 feet from the west wall of the engine-room. The arrangement of the switchboard and conductors was next described.

The battery-room has a fire-proof floor covered with acid resisting asphalt. The battery consists of 132 cells of the new Crompton-Howell 31-plate type. It is divided up into two half-batteries, positive and negative, and is arranged in two tiers on four rows of stands, which are of cast-iron, with wooden longitudinal bearers carrying the cells; the eight hospital cells are arranged on separate stands. All the cells are similar, and have each a nominal capacity of 1000 ampere hours, the normal rate of discharge being 200 amperes. The battery has ample capacity to meet the whole of the load of the station from daylight till the evening; thus during the summer time it can do the lighting during more than half the twenty-four hours. The high-tension portion of the station consists at present of only two engines and alternators with their switchboard, and the rectifiers for arc-lighting with their regulating arrangements and switchboard; but in the immediate future, this plant will be considerably extended. Each of the alternators is driven direct by a Willan's three-crank engine of 150 I.H.P., on the same bed-plate. The alternators are of the "Portsmouth" type, with some modifications necessary owing to their increased speed of 450 revolutions per minute. Their armatures are stationary, and are of great strength; the core, consisting of sheet-iron segments, is solidly bolted into the framing of the machine, with the coils threaded through holes in the sheet-iron, well insulated, and completely enclosed in brass boxes. The field magnets revolve, and consist of two heavy cast-steel discs, having on their circumference claws projecting sideways alternately over the field winding, which is between the discs, and is well protected from injury. The exciting current is taken from the low-tension switchboard at 230 volts, and is only a few amperes. The alternators work at an electromotive force of between 2000 and 2200 volts with a frequency of 52½ figures complete alternations per second. Opposite to the alternators, and standing on the same foundation block, are placed the Ferranti rectifiers for the series arc-lighting. These are three in number, one for each of the two circuits, and one to spare.

In the three-wire system of distribution for the northern and central districts, the electromotive force between the two outer conductors, positive and negative, is 230 volts, while that between the middle wire and the positive or negative is 115 volts. The latter is the electromotive force of the lamps on the consumers' premises, no trouble being now experienced in obtaining glow-lamps to work at this electromotive force, or even higher. The feeders from the station are connected to the distributing mains at sixteen points. They consist of two conductors only, the positive and negative; the middle wire is inter-connected throughout as much as possible, and is brought back from three districts on the system. The cables are put in parallel at the station, and one connection only is made to the switchboard. The positive and negative sides respectively of all the feeders are put in parallel at the switchboard; but any feeder or feeders can be put on a separate machine if required. As far as possible, consumers in each street and district are balanced against one another by connecting them alternately between positive and middle wires, and between negative and middle wires; large consumers have all three wires taken into their premises, and their lights balanced against one another in a similar manner. But however carefully this balancing is done, it is impossible to get a really accurate balance; the "out of balance" current varies from hour to hour, and even from minute to minute, and is different on different days of the week. The amount out of balance is compensated for at the station by means of the balancing machines, one of which can be put on either side of the system; the balancing during the light load is done from the battery alone. Light wires, forming potential leads or pilot wires, are brought back from all three conductors at each feeding point, and are connected to the feeder volt meters on the switchboard; so that the pressure at the feeding points at any part of the system is directly known at the station, and the necessary regulation made for keeping the electromotive force constant. The distributing mains are brought back to the station, but are used only for the supply of light and power there; no regulation is done on the mains anywhere, except to the feeding points. No high tension feeders or distributing mains have yet been laid, but will be added later.

In regard to road-work, practically the whole of the distributing mains are laid as cable insulated with india-rubber

heavily braided, drawn into Doulton stoneware casing under the footways, and into either Crompton-Davis cast-iron casing or cast-iron pipes under the roadways. At all crossings, and at intermediate places on the foot-ways, brick junction boxes are built. Wherever sufficient space has been found under the footways, the feeders have been laid as bare copper strip, carried on stoneware insulators in concrete culverts. Across all roads, and where there has not been sufficient space for culvert, the feeders are laid in Siemens armoured cable, laid direct in the ground. All the feeders have been designed to have a total drop of 44 volts at full load Potential leads, by which each feeding point is connected back to the station, consist each of three sets of wires, insulated with specially prepared paper, laid up together and covered with the same material, a lead tube being drawn over the whole. All of the cable connections are made by cone connectors, sweated on to the cables, and fitting into gun-metal connecting blocks.

The author concluded by stating that he had endeavoured to describe the arrangement of the plant and mains, and any details in their design and construction which might be of interest, without discussing general principles or the advantages or disadvantages of any individual system.

In the discussion which followed the reading of the paper, the chief point raised was the advisability of using a dual system of supply; but the author very well disposed of the objections raised in this direction by pointing out that the area to be dealt with consisted of two districts differing widely in character. For one the high pressure alternating system was most desirable, and for the other a low tension system. It is easy, as Mr. Burstall said, to maintain that either system is wrong if the disadvantages of that system are given undue prominence, and the advantages of the rival system are brought prominently forward. Of course, the benefit of the high-tension alternating system consisted in the saving of copper, but that was a thing that perhaps would not work out in practice exactly in the same way as it was presented in theory. On paper, a larger main was required for low-tension transmission, but practically there was often no saving in copper As a matter of fact there is, however, an economy in material in the feeders. It becomes a question of balance of advantages, whether certain points shall be sacrificed to the saving of copper. Mr. Burstall stated that so far as Edinburgh was concerned, no less than six schemes were worked out in detail before it was decided to adopt the plans described in the paper. The discussion also ranged over the question of superheating steam, the efficiency of feed pumps, and various other engineering details, which, however, it is not necessary here to consider in connection with an electrical paper, especially as no new facts of importance were added to one's information upon these matters.

The second paper, on the Lille experiments with ropes and belts, does not need any extended notice at our hands. The Société Industrielle du Nord de la France had the question of transmission of power brought before them by a paper by M. V. Dubreuil, and it being considered advisable to obtain more information on this subject, a commission was appointed, and the Institution of Mechanical Engineers was invited to send a representative. Various trials were made with ropes and belts under different conditions. Owing to the want chiefly of dynamometer records, no very exact figures could be deduced from the experiments, so far as the actual power transmitted was concerned. An effort was made to make the experiments comparative as between ropes and belts, by keeping the experimental conditions in both cases constant. It is somewhat doubtful, however, to what extent these efforts were attended by success. Generally speaking, it may be said that the results arrived at showed the power absorbed by transmission to be equal, whether ropes or belts were used. This conclusion, however, must be accepted with some reserve.

Prof. Capper in his paper, commenting on the experiments, attempted to arrive at some conclusion as to the efficiency of the whole system. His figures were excellently worked out, but he himself acknowledged that the data upon which he based his calculations might be open to question Although, therefore, the experiments may not be of great use to future designers of machinery, the thanks of English engineers are none the less due to the Société Industrielle for their courtesy in inviting the Institution of Mechanical Engineers to send a representative to watch the proceedings. The Institution is also to be congratulated in being able to send so competent an observer as Prof. Capper as their representative.

A long discussion followed the reading of the paper, which occupied the rest of the evening. Perhaps the most interesting part of it were the remarks of Mr. Crompton, who stated that the question of transmission by ropes and belts did not possess any longer the importance it once did, as within a few years the silent, flexible connecting rod, called electricity, would supersede all other methods of transmission, so that ropes and belts would only be found exhibited in museums, as mechanical curiosities of a past era.

RECENT FISHERY LITERATURE.

The general report for 1894 of the Fishery Board for Scotland contains evidences of the revolution which is quietly but steadily effecting a complete change in the methods of the fishing industry. There is a further falling-off in the number of fishermen and fishing boats engaged in the herring and line fishing. The sailing craft continue to give way before steam trawlers and steam liners, and the competition for the best markets is bringing about an increased centralisation of the fishing industry. The smaller and healthier creeks and villages are being gradually depopulated, and the larger ports are becoming overcrowded. The summer herring fishing is being forsaken for line fishing, which can be prosecuted all the year round. Steam liners are consequently increasing rapidly in number, and during the past year have proved most successful. Indeed, in spite of the falling off in the means of capture, the decrease in the total quantity of fish landed, as compared with the returns for 1893, amounted to only 19,000 cwts. This state of things may be attributed to the fact that the steam trawlers and liners are able to proceed much further out to sea than sailing craft, and are able to fish over fresh grounds where large catches are frequently obtained. Being larger and stronger, moreover, these vessels are to a great extent independent of wind and weather, which seriously affect the movements of the smaller sailing boats. Herring were locally plentiful, and of a quality never excelled within modern times. They were especially abundant in the Orkneys and Shetlands—where the catch was double that of 1893—and in the Campbelltown area; but the herring fishery in the Hebrides was again a failure, and this is the more to be regretted as Stornoway, the most important centre for ling, also exhibited a large falling off in the returns of the latter fish. It is gratifying to notice a slight increase in the returns of flat fish, especially in view of the complaints of the depletion of grounds frequented by them. The increase may, however, be due to the hauls made by steam trawlers working on fresh and more distant grounds. For the first time in the Board's returns, a table is given of the number of persons engaged in Scotch fisheries on sea and land; there are more than 117,000 people taking some part in the various branches of the industry.

The report of the same Board on Salmon Fisheries shows that the season of 1894 was in most districts below the average. On the other hand, salmon disease appears on the whole to have been less prevalent during 1894 than in the previous year.

In an interesting and amusing article on the North Sea fisheries ("Journal of the Marine Biological Association," vol. iii., 1895), Mr. Holt devotes especial attention to the question of the destruction of immature fish. The fact that there has been a diminution of the fish supply during recent years seems to be thoroughly established, although the improved boats and methods of fishing render this decrease less striking than might otherwise be the case. The alleged cause of this diminution is over-fishing, that is to say over-trawling, but inshore trawlers, shrimpers, and other fishermen do not appear to be blameless in the matter. During some years' residence at Grimsby, Mr. Holt has collected statistics on this question. They are necessarily incomplete, as time and opportunity did not permit of wide investigation; they are, however, fairly complete in the case of the plaice, one of the most important of our flat fishes, and Mr. Holt's evidence concerning this fish is very striking. He states that during a whole year's trawling on the North Sea grounds 57 per cent. of the plaice brought to shore were sexually immature, and had thus never had a chance of reproducing their species, and so contributing to the maintenance of the supply. In the Conference of 1892 the size limit for plaice was made 10 inches; they are marketable at this size, although not sexually mature, for Mr. Holt finds that as a rule North Sea plaice are not mature until they attain a length of 17

[illegible] Fish vary in size under different conditions and in different areas, and on the south-west coast the limit of size for maturity in plaice is 13 inches according to Mr. Cunningham. An immense number of the small plaice brought to market are caught on the eastern grounds; and this area forms also a nursery and spawning haven for turbot, brill and soles. The number of plaice above 10 inches on these grounds is inconsiderable; and if a size limit of 13 inches for plaice brought to market were enforced, even during the spring and summer only, such a law would suffice to keep trawlers off these grounds, which would thus be left unmolested. In conclusion, Mr. Holt considers various remedial measures for checking the depletion of the North Sea grounds, and of enabling the fish supply to recover; but the only practicable method of attaining this end at present is by legislation based on the principle of the size limit.

THE FORMATION OF BACTERIAL COLONIES.[1]

The author has examined the details of development of the colony from a single spore, in numerous species, by employing microscopic plate-cultures, which can be kept under observation under a one-twelfth and even a one-twentieth oil immersion, or by making pure *Klat. hpraparate* of the growing colony on cover-slips covered with a thin film of gelatine.

He finds many factors of importance in affecting the form, extent, rapidity of growth, and other characters of colonies. The consistency of the gelatine, the presence of moist films on the surface of the gelatine, the rate of (slight) liquefaction, &c., all being of importance in explaining the shapes, &c., of submerged colonies—"whetstone shaped," moruloid, spherical, or lobed colonies—the mode of emergence and spreading over the surface of the gelatine, the formation of radiating fringes, iridescent [illegible], &c.

Exposure to light during the development of liquefying colonies may profoundly affect their shape and other properties, a phenomenon closely connected with the retardation of liquefaction and growth. Pigment bacteria may give rise to perfectly colourless races when cultivated under certain conditions, and the colour restored by again changing the conditions, a fact which the author has not only confirmed with red forms, but which he shows to be true of a violet bacillus. Species commonly described as non-motile show active movements under certain conditions, and the sizes of bacteria are not constant in different regions of one and the same colony. Details have been worked out for series of types, the extremes of which differ considerably in liquefying power, and essential difference in the appearance of a colony may depend on the amount of liquefying power evinced.

Some curious cases of travelling films, the lobes and contorted [illegible] of which move like amœbæ over the surface of the gelatine, were also examined.

The facts point to (1) differences in colonies even of one [illegible] may depend on much more subtle differences in cultures than are usually recognised; (2) varietal differences may occur [illegible] bacilli of the same species (isolated from the river), due to different vicissitudes the two individuals have been subjected [illegible] during their sojourn in the water; (3) the difficulties met with in diagnosing "species" of bacteria with the aid of works of [illegible] authority, are partly due to varieties of the same species [illegible] recorded by different observers under different names, and the author thinks some more consistent pre-arranged plan of [illegible] out the characters of such forms should be developed by [illegible] than at present exists.

A False Bacterium.

The author has isolated from the Thames a form which gives [illegible] ordinary reactions of a bacterium in plate-cultures and [illegible] gelatine, agar, potato, broth, milk, &c.

It is a rod-like form, 1 μ thick, and up to 2 or 4 μ long, stains [illegible], and cannot be distinguished from a true Schizomycete by the methods in common use.

On cultivating it under high powers—one twelfth and one-twentieth oil immersions—from the single cell, however, it is [illegible] to form small, shortly branched mycelia, the growth and segmentation of which are acropetal. This turns out to be a minute oidial form of a true fungus.

Its true nature can only be ascertained by the isolation and culture through all stages from the single cell, according to the original methods of gelatine cultures of Klebs, Brefeld, and De Bary, which preceded and suggested the methods employed by bacteriologists; and the facts discovered raise interesting questions as to the character of alleged "branching" bacteria on the one hand, and the multiple derivation of the heterogeneous group of micro-organisms, termed bacteria in general, on the other.

[1] [illegible] Section K of the British Association [illegible] H. Marshall Ward, F.R.S.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The following have been appointed Examiners in Natural Science for the current academical year:—Physics: Dr. O. J. Lodge, F.R.S., and Mr. L. R. Wilberforce. Elementary Physics: Mr. H. F. Newall and Mr. S. Skinner. Chemistry: R. Meldola, F.R.S., and Mr. W. J. Sell. Elementary Chemistry: Mr. F. H. Neville and Dr. S. Ruhemann. Mineralogy: Prof. N. Story-Maskelyne, F.R.S., and Mr. H. A. Miers. Geology: Prof. G. A. J. Cole and Mr. H. Woods. Botany: Dr. H. M. Ward, F.R.S., and Mr H. Wager. Zoology: Prof. S. J. Hickson, F.R.S., and Mr. S. F. Harmer. Elementary Biology: Mr. A. C. Seward and Mr. J. J. Lister. Anatomy: Prof. A. Macalister, F.R.S., and Prof. A. M. Paterson. Physiology: Mr. W. B. Hardy and Prof. W. D. Halliburton, F.R.S. Pharmaceutical Chemistry: Mr. A. Ivatt and Mr. R. H. Adie.

Dr. Glaisher, F.R.S., and Mr. R. T. Glazebrook, F.R.S., of Trinity College, and Prof. G. B. Mathews and Mr. A. E. H. Love, F.R.S., of St. John's College, have been appointed Examiners for Part II. of the Mathematical Tripos; and Prof. Ewing, F.R.S., Prof. Reynolds, F.R.S., and Mr. J. B. Peace, of Emmanuel College, have been appointed Examiners for the Mechanical Sciences Tripos.

The twenty-second annual report on the local lectures has just been issued. It touches upon a number of interesting questions. Of the work temporarily undertaken for County Councils three years ago, the only portion that remains vigorous is that carried on in connection with the Norfolk County Council in the preparation of teachers in elementary schools to teach science subjects in evening classes. These courses, given in the county of Norfolk, have been supplemented by practical laboratory work in Cambridge during the Long Vacation, which has been attended by teachers holding scholarships from the Norfolk Council. The Syndicate state in the report that they are persuaded that this is a work of great value, and that they believe that it is in this direction, rather than by the provision of ordinary technical courses for rural audiences, that they can now best aid the technical education work of County Councils. During the past session the scheme of certificates has been remodelled so as to encourage more continuous and systematic work, and has already begun to show good results. The most important part of the report is that in which the Syndicate announce their intention to appeal for funds to enable the University to develop and extend the work in a more systematic way by placing particular districts in charge of superintendent lecturers, who will form a direct link between the district and the University. Appended to the report is a special report by Dr. R. D. Roberts, the secretary for lectures, in which a large scheme for the future development of the work is sketched and practical proposals suggested.

A Directory of Science, Art, and Technical Colleges, Schools, and Teachers in the United Kingdom, by Mrs. R. S. Lineham, has been published by Messrs Chapman and Hall. The directory will undoubtedly prove of great value to all who are concerned with scientific and technical education. It contains a list of schools arranged alphabetically according to towns, with the names of secretaries, principals, and teachers, and the number of students taught in each subject. There is also an alphabetical list of names and addresses of teachers of science, art, and technology, arranged under the headings of subjects taught. Other information of particular use to teachers under the Science and Art Department, and needed now and then by all promoters of elementary scientific education, will be found in the volume. Complete the directory is

not, nor is it infallible; but it is a praiseworthy attempt to organise into one guild the teachers of a growing and most important section of educational work. The labour involved in getting together the facts which make up the contents must have been immense, and it is to be hoped that, now the work has been done, the support required to ensure the annual publication of the directory will not be lacking. If the book only makes teachers in technical schools and institutes realise that they are part of one organic whole, having for its object the extension of scientific knowledge, it will accomplish a much-desired end.

THE Report of the Technical Educational Committee of the Berks County Council is optimistic, but it is not distinguished by descriptions of any very noteworthy developments. Berkshire is an agricultural county, and that is tantamount to saying that little encouragement is given to scientific education. Such counties are not willing to be taught much about principles; what they will tolerate, are subjects like practical butter-making, laundry-work, poultry-keeping, hedging, and horse-shoeing; but to attempt to teach agriculturists anything much beyond manual dexterity, is to court opposition. However, the Technical Education Committees are doing something to educate the agricultural mind to a better appreciation of the benefits to be derived from science, though it must be confessed that the rate of progress is extremely slow. Berkshire, along with Oxfordshire and Hampshire, contribute towards the maintenance of the University Extension College at Reading, and, in recognition of the satisfactory development of the agricultural department of the college, the Board of Agriculture recently granted a sum of £500, and the money could not have been better bestowed. The various courses of study at the college are well arranged, and valuable field experiments are carried on. By paying over the sum of £400 to the college, the Berkshire Committee ensures efficient instruction for the students under their care, and that is a very important consideration, for the supply of good teachers, competent to teach science as it should be taught, is comparatively small, to say nothing of the laboratory accommodation essential for truly scientific instruction. In spite of the facilities thus offered, the lectures in elementary science arranged for teachers were not successful. It would be a great pity if the Committee had to discontinue this part of their work on account of the want of support by the teacher for whom the lectures are intended. The other ways in which the Committee disposes of the funds allocated to technical education are evening continuation classes, scholarships, dairying, farriery, and bee-keeping. Aid is also given to classes in the principles of agriculture, mensuration, botany, drawing, horticulture, chemistry, mechanics as applied to agriculture, and to manual instruction in woodwork and metalwork.

THE Brussels correspondent of the *Times* reports that the electrical and anatomical institutes founded by M. Ernest Solvay, and presented by him and other donors to the University of Brussels, were officially inaugurated on Monday, under the presidency of the Burgomaster, assisted by M. Graux, the Chancellor, and the entire body of professors. Delegations from the English and Continental Universities have responded to the invitation of the Brussels University to take part in the series of *fêtes* organised in celebration of the event.

IT was announced a few weeks ago that the Treasury has thoughts of reinstating King's College, London, in the enjoyment of its share of the grants made to University Colleges. In consequence of this decision, the Council of the College have adopted a conscience clause as a standing regulation.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, October 25.—Mr. Walter Baily, Vice-President, in the chair.—Prof. J. Perry read a paper, by himself and Mr. H. F. Hunt, on the development of arbitrary functions. During the discussion on Prof. Henrici's paper (April 13, 1894), one of the authors described a graphical method of developing any arbitrary function in a series of other normal forms than sines and cosines, such as Bessel's or zonal spherical harmonics. The method consisted in wrapping the curve which represents the function round a specially shaped cylinder, not circular, and projecting this curve on to a certain plane. Many months were wasted in finding with great exactness a sufficient number of coordinates of the trace of the cylinder suitable for a Zeroth Bessel development. The labour, however, was unnecessary, since the coordinate most troublesome to calculate is not really needed, the projection only taking place in one direction. To develop any arbitrary function of x (say y) in normal forms, the real difficulty consists in finding the value of an integral such as $\int_0^a y.\ Q(x).\ dx$ where $Q(x)$ is some tabulated function. If now z is another tabulated function which is the integral of $Q(x)$, the required integral is $\int y dz$. If the values for y for 25 equidistant values of x are known, from $x = 0$ to $x = a$. Let the corresponding values of z be tabulated, and let a curve be drawn with the values of y as ordinates and the values of z as abscissæ; the area between the axis of z and this curve gives the value of the integral required. The authors give four tables containing the abscissæ for the four first terms in the development in Zeroth Bessels. They have tested the method by applying it to the calculation of a known function in terms of zonal spherical harmonics, and the agreement between the true value of the coefficients and those found is very satisfactory. Prof. Henrici said the method was a new departure, since in the place of an instrument of complicated design the authors only used a planimeter and pencil and paper, and obtained the same degree of accuracy. The fact that the series employed to test the method consisted of a finite number of terms seemed to him an objection. Prof. Karl Pearson had in a recent conversation informed him of a method for the development of functions which he (Prof. Pearson) had recently discovered. This method was not, however, so simple—at least in most cases—as that of the authors. Prof. Minchin thought it would add to the intelligibility of the paper if it were stated that the method was similar to that employed when expanding in terms of a Fourier series or in spherical harmonics. In these cases you have a function which, when multiplied by other functions of different orders, kills all the terms except one. Graphic methods ought, in his opinion, to be very much oftener employed, and he considered that there was no problem in physical mathematics of which the solution could not be obtained by graphic methods. He would also like to know if Prof. Perry had obtained a graphic method of calculating Bessels. Mr. Trotter agreed with Prof. Minchin as to the neglect of graphic methods. He regretted that Prof. Perry did not continue to consider the method as the projection from a cylinder, as he had found the method of wrapping curves round a cylinder most useful. Prof. Perry in his reply said he had adopted the expansion they had employed, under the impression that the test was a particularly severe one. He had not discovered a graphic method of calculating Bessels. The reason they gave up the cylinder was the immense labour involved in calculating the y coordinates of the trace, which would afterwards be of no use in the development of the function.—Mr. F. W. Lanchester read a paper on the radial cursor, a new addition to the slide-rule. The ordinary form of slide-rule enables calculations to be made which involve multiplication and division, also involution and evolution where the indices are integers. The radial cursor allows of the solution of problems in which fractional indices occur; for example, in questions involving the adiabatic expansion of a gas, where an expression of the form $pv_\gamma = \text{const.}$ has to be dealt with, and where γ is not an integer, nor is it constant for all gases. In this case it is necessary to provide some ready means of dividing the scales on the rule and slider proportionally to the value of γ, which corresponds to the division and multiplication of the respective logarithms of the quantities dealt with in the proportion of the indices of p and v, *i.e.* 1 and γ. This proportionate division of the scales is effected in the new cursor by a radial index-arm which is arranged to swing about a stud fixed to a sliding-bar running in guides at right angles to the rule. All readings are taken at the points of intersection of a line on the radius arm and the edges of the slide. The distance of the pivot, on which the radius arm turns, from the scale, and therefore the value of the index employed, is read off on a scale fixed to the transverse bar. Mr. C. V. Boys said that owing to the kindness of the author he had been able to try the cursor, and had found it of great service in dealing with questions of adiabatic expansion. The new addition to the slide-rule suffers under the same disadvantage as the rule itself, namely that a verbal or written description seems so very much more complex than is the actual operation when using the rule. The author's device might be described as an india-rubber slide-rule, for it performed the function of a slide-rule in which the graduations

[illegible] so [illegible] rather so that the ratio of the length [illegible] the rule is the length of the scale on the [illegible] at will, and thus involution and evolution [illegible] performed. Mr. Blakesley asked how [illegible] were dealt with. Prof. S. P. Thompson [illegible] Mr. [illegible] expressed their admiration for the author's [illegible] "stretching" the scale. Mr. Burstall said he had [illegible] apply a similar method to the Fuller rule, but did not [illegible], since in this scale there was only one scale. He [illegible] author's method could be applied in a form such that a greater accuracy than one in 500 could be obtained. Mr. [illegible] thought the fact that the point of intersection of two lines [illegible] acute angle had to be read was likely to limit the [illegible]. The author having replied, the Society adjourned [illegible] November 8.

PARIS.

Academy of Sciences, October 21.—M. Marey in the chair.—The decease of M. Hellriegel (Correspondent of the [illegible] Section), at Bernburg, Anhalt, on September 24, was announced to the Academy.—A study of graphite extracted from a pegmatite, by M. Henri Moissan. The author concludes, from the impressions of markings on the graphite crystals transferred to surrounding quartz and felspar, that the graphite existed before the pegmatite was formed. This graphite much resembles graphite formed in the electric furnace in fused metals, and may have been formed under somewhat similar conditions.—A study of some varieties of graphite, by M. Henri Moissan. Graphites found in nature may be divided, as recommended by M. [illegible], into intumescent and non-intumescent graphites. The former appear to have been produced in fused [illegible], the latter by the action of a raised temperature on [illegible] amorphous carbon.—On the Mounier Observatory, by M. [illegible]. Details are given concerning observations on the surface of Venus. The lack of alteration in the [illegible] part of the surface viewed during a con[illegible] supports Schiaparelli's contention that the planet [illegible] with great slowness.—M. Mascart presented an "Atlas of the 'isanomals' and secular variations of terrestrial magnetism," by M. M. de Tillo. The general conclusions able to be drawn from a study of the lines of secular variation are: (1) the changes of the elements so occur that in one hemisphere they are positive, and in the other negative; (2) there is a great similarity between the trend of the isanomals and that of the lines of equal secular variation.—Prof. Norman Lockyer presented [illegible] spectra taken with an objective and [illegible] by the Brothers Henry. The lines in the spectrum [illegible] correspond to those of helium. The absorption due [illegible] of stars showing few lines is due mostly to [illegible].—The following articles, by M. Cruls, are [illegible] Correspondence: (1) Posiçoes geographicas. The [illegible] determined are those of Rodeio, Entre-Rios, [illegible], and Barbacena, along the Central [illegible]. (2) [illegible] de Rio. Given by [illegible] from 1851 to 1890. (3) Eclipses de Soleil [illegible].—On a long period inequality in the longitude of [illegible]. An empirical correction proposed by [illegible] to the Le Verrier tables of geocentric longitude, and [illegible] want of sufficient precision in the determination of the value of a coefficient, is shown by the [illegible] by an independent method not to be [illegible] error in the tables, as his results agree exactly [illegible].—On the deformation of surfaces, by M. [illegible].—A correction to be applied to readings of [illegible], by M. Scheurer Kestner. The correction [illegible] applied to the Walferdin or Beckmann [illegible] for the mercury in the upper reservoir, [illegible] regards expansion shown [illegible].—Study on the latent heats of vaporisation of fatty [illegible], and of diethyl and dimethyl carbonates, by M. W. Longuinine. With regard to Trouton's formula $\frac{M l}{T}$ = constant (where M is the molecular weight of the substance, l its latent heat of vaporisation, and T its absolute boiling point), the results so far obtained warrant the general conclusions: (1) For each of the groups that have been studied $\frac{M l}{T}$ is very nearly constant. (2) It varies notably for different groups of substances. Latent heats may be calculated by the [illegible] value given to the constant within 1·5 per cent., and by [illegible] obtained from a determination by means of a substance of the same type within 1·5 per cent.—Peroxidised potassium derivatives of benzoquinone, by M. Ch. Astre. Benzoquinone contains only two atoms of hydrogen in its molecule replacable by a metal. The diketonic nature of benzoquinone is supported by the author's results.—On the composition of rice imported into France, by M. Balland.—On the toxicity of acetylene, by M. N. Grehant. Acetylene is poisonous when it occurs in air to the extent of 40 to 70 per cent., but is not nearly so injurious as ordinary lighting gas. M. H. Moissan added that pure liquefied acetylene possesses an agreeable ethereal odour, and causes no inconvenience when breathed in small quantity.—Serotherapy in the treatment of cancer, by MM. J. Hericourt and Ch. Richet.—On a new Lamellibranch (*Scioberetia australis*) commensal with an Echinoderm, by M. Felix Bernard.—On the age of the lignite formation of Southern Chili, the Arauacaria group, the Chilian equivalent of the Laramie and Chico-Tejon group of North America, by M. A. F. Nogues.—On the daily variations of relative humidity, by M. D. Eginitis.—On new observations in the Padiriac chasm (Lot), by M. E. A. Martel.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Elementary Physics: J. Henderson (Longmans).—The People of the Moon: T. Carter (Electrician Company).—An Account of Palmyra and Zenobia: Dr. W. Wright (Nelson).—Rambles in Japan: Dr. H. B. Tristram (R.T.S.).—Technical Educator, Vols. v. and vi. (Cassell).—Birds of Berwickshire: G. Muirhead, Vol. 2 (Edinburgh, Douglas).—Practical Trigonometry: H. Adams (Whittaker).—The Valley of Kashmir: W. R. Lawrence (Frowde).—Atlas of the Fertilization and Karyokenesis of the Ovum: Drs. Wilson and Leaming (Macmillan).

PAMPHLETS.—Anleitung zur Molekulargewichtsbestimmung: Dr. G. Fuchs (Leipzig, Engelmann).—Ueber den Zusammenhang Zwischen der Erdmagnetischen Horizontalintensität und der Inclination: Dr. H. Fritsche (St. Petersburg).—Compte Rendu des Travaux de la Société Helvétique des Sciences Naturelles reunie a Schaffhouse 1894 (Genève).—Congrès de la [illegible] Atmosphère, Anvers, 1894 (Anvers).—Communications: A. [illegible] (Anvers).

SERIALS.—Tufts College Studies, No. 4 (Tufts College, Mass.).—Zeitschrift für Wissenschaftliche Zoologie, lx. Band, 1 Heft (Leipzig, Engelmann).—Studies in Biology from the Biological Department of the Owens College, Vol. 3 (Manchester, Cornish).—Good Words, November (Isbister).—Sunday Magazine, November (Isbister).—Longman's Magazine, November (Longmans).—Journal of the Royal Microscopical Society, October (Williams).—Mittheilungen der Naturforschenden Gesellschaft in Bern, Nr. 1335-1372 (Bern).—Verhandlungen der Schweizerischen Naturforschenden Gesellschaft, 1894 (Schaffhausen).—Scientific Transactions of the Royal Dublin Society, Vol. v. series 2: The Papillary Ridges on the Hands and Feet of Monkeys and Men: D. Hepburn (Williams).—Humanitarian, November (Hutchinson).—Astrophysical Journal, October (Wesley).—Natural Science, November (Rait).
